These improvements mainly consist in the construction and employment, in reaping and mowing machines, of an apparatus constructed as hereafter described for collecting the cut crop and delivering it in sheaves from the side of the machine. This apparatus consists of an endless chain carrying rakes, which pass above and below the platform; it is supported by a fore carriage in the form of a sledge, carrying the finger beam and knife, and jointed to a hind carriage mounted on wheels. The fore carriage is supported upon two metal bars in preference to rollers, which have been found to enter the soil, grass, or straw, with which they come in contact and become entangled or charged therewith; it is supported at the rear by a train of wheels fixed to the frame, the side bar of which has a groove formed in it, covered by plates forming sockets, and uniting the frame and one of the metal bars before mentioned, whereby the necessary joint is formed for uniting the two carriages, and the fore part and cutting apparatus are enabled to follow the undulations of the soil. The outer end of the axle, on which the train of wheels is mounted, has a series of holes in it, whereby the position of the bearing or running wheel may be altered so as to equalize the resistance offered by the crop. This arrangement is intended to remedy the inconvenience arising in ordinary reaping and mowing machines from the knife moving obliquely in proportion to the strength of the crop. A toothed wheel, with spring clutch on the wheel axle, transmits motion through wheels and jointed rods to the knife. The separator or divider is fitted with a cutting blade for cutting the grass or other herb which will not separate, and which would otherwise clog it, and which is delivered on to the platform. The reel for throwing the corn to the knife has rotary motion imparted to it through

a pulley on its own shaft, communicating by a band with another pulley on a shaft, receiving motion from a pulley on the same shaft as that communicating motion to the knife. The rake chains have motion communicated to them across and round the platform by belts and bevelled wheels driven from the main wheels of the machine. The motion communicated to the rakes causes them to deliver the cut crop in sheaves or bundles on the left side of the machine at regular intervals. The pole is supported and held by a moveable bolt to a bar rising from the fore carriage, in which several holes are pierced in order to raise or lower the point of traction according to requirement. The driver's seat is placed at the rear of the machine; the driver has the whole of the machine before him, and has the working parts wholly under his control, and can with his foot throw the knife out of gear and stop the machine when he desires. This seat is placed to the left of the machine, so that its weight and that of the driver may counterbalance that of the knife carrier. If, however, this is not sufficient, a weight may be suspended from the seat and frame, so that the driver, by moving out of his seat to the left, may raise the knife carrier. This machine is with facility moved from place to place, and can be easily altered from a reaping to a mowing machine, and *vice versa*. *Patent abandoned.*

1074. R. A. Brooman. *Improvements in carriages for transporting loads on railways, common roads, and other surfaces.* (A communication.) Dated April 14, 1862.

The object of this invention is to facilitate the transport of loads over railways, common roads, and other surfaces, and it consists, first, in the employment of an elongated hollow drum, with rounded edges, which are made to serve as rails to guide the rollers hereafter described; second, in the employment of a platform or truck for receiving the load which is fitted above or inside the hollow drum; third, in the employment of rollers arranged in pairs or separately, and held together by moveable iron or steel links, forming closed or endless chains of moveable rollers, which are free to rotate round the drum and support it and the load, all as hereafter described. The invention is not described apart from the drawings. *Patent completed.*

1075. R. A. Brooman. *Improvements in Pumps.* (A communication.) Dated April 14, 1862.

The characteristic feature of this invention of improvements in pumps is the employment of two shafts, together with inclined pump barrels and pistons, as hereafter explained. One of the shafts is inclined at any desired angle, and the two shafts are coupled together by a universal or other joint, ensuring the same speed to both, and causing them to revolve in the same direction. One of the shafts carries through a horizontal disc, or cross-bars, a pair or more of pump-barrels, set at the same angle as the inclined shaft, while the other (say the inclined shaft), has fixed in the lower part an inclined cross-head, with rods and pistons, also inclined to correspond with and work in the pump-barrels. A vessel or case, fitted with a cover, which may be removed when required, has a suction-pipe fitted at the lower, and a discharge-pipe at the upper part. Both pipes are provided with suitable valves, and in this vessel the barrels and pistons are enclosed. The pump-barrels (say four) are suspended from the under side of the horizontal disc or cross-bars in such manner as to be able to adapt themselves to the inclinations of the pistons. A ring of some strong, flexible material unites and keeps the pumps water and air-tight, so that the top of the pump-barrels is in communication with the discharge, while the bottom of the pumps is in communication with the lower part of the vessel. A diaphragm may, if desired, surround the lower part of the plate. *Patent completed.*

1076. R. A. Brooman. *An improved hobby-horse.* (A communication.) Dated April 14, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1077. C. J. Coxhead. *Improvements in pianoforte actions.* Dated April 15, 1862.

Here the flys or hoppers are attached to the hammer butts, and work in a downward or inverted form; they are met on the keys by blocks with notches and hollows in them, clothed in the usual way; the ends of the flys or hoppers work off the notches into the hollows in the act of percussion. The hammers and flys or hoppers are made to return to their places after percussion by one spring, attached to each hammer and fly (conical, spiral, or otherwise, to be used either back or front), which acts on both, one end on the hammer butt and the other end on the fly or hopper, thereby obviating the necessity of any more springs or tapes to make the hammers return after percussion. The hammers escape from the strings by arms that project from the flys or hoppers, and are regulated by escapement buttons screwing on to the arms, or on to the rail above which the arms strike against. The hammers are checked by checks fixed on the notch blocks on the keys, and pass by the escapement arms and meets the stops that project from the hammer butts, the ends of the flys or hoppers at the same time stopping in the hollows below, and are hindered from going too far back by a piece of felt or other springing substance, which is placed between the hammer-rail and flys or hoppers, thereby securing a firm check and prompt repetition. The dampers consist of wires, bent in the form of quadrants, and have the damper heads attached to one end to meet the strings; the quadrant wires then pass through a socket, and work on the front ends of the damper levers, which act on centres; straigh wires are attached to the back ends of the levers, and pass through another socket at the back of the hammer-rail, and meet the end of the keys, and are regulated by buttons screwing on to the wires or keys. Weights or springs are a tached to the wires to cause the dampers to press against the strings when the fingers are removed from the keys. *Patent abandoned.*

1078. G. Fell and W. Haynes. *Improvements in machinery or apparatus to be used in the manufacture of leather.* Dated April 15, 1862.

Here the patentees cover a roller, drum, or cylinder, with emery, sand, pummice-stone, ground glass, or other rough cutting substance, or face it with rough metal, similar to a file. The roughened roller, drum, or cylinder is placed in suitable bearings, and has a rapid revolving motion imparted to it by power. The skins or hides are placed in contact with the rough surface of the roller, drum, or cylinder during its rapid motion, by which the operations commonly called shaving, paring, whitening, grounding, buffing, and softening are performed on sheep, goat, calf, seal, deer, or other skins or hides, by the friction or grinding action of the roller, drum, or cylinder. *Patent completed.*

1079. J. Taylor. *Improvements in machinery or apparatus for preparing cotton or other fibrous materials to be spun.* Dated April 15, 1862.

This relates to improvements in the carding engine, and consists in employing a circular stripper, consisting of a roller with a number of knives or combs working in slots or grooves. The knives or combs are acted upon by eccentrics, cams, tappets, or other suitable means, with a revolving motion, so as to cause the said knives or combs to project one after the other beyond the periphery of the roller, in order to strip the doffing cylinder, and then return into their slots or grooves. *Patent abandoned.*

1080. T. H. Bennett. *Improvements in the manufacture of hats, caps, or other coverings for the head.* Dated April 15 1862.

The patentee manufactures hats, caps, or other coverings from or with a combination formed by a drummed perforated leather, and a grease-absorbing material, such as prepared cotton, flannel, felt, horse hair, sponge, or any other absorbing and retaining material that will answer the purpose. He perforates the drummed leather at that portion which presses against the forehead when the perfect hat is worn. He perforates either in a single, double, or more lines of holes. Above these perforations, and as high up the leather as he finds requisite, he places a strip of the prepared absorbing material, this material lying immediately above the holes; and between the drummed leather and the inside of the body of the hat, forms a species of air chamber, and prevents the grease from passing beyond the strip of cotton (or other material) before mentioned. *Patent completed.*

1081. F. A. Le Mat and C. F. Girard. *Improvements in the construction of revolving and repeating firearms, part of which invention is also applicable to other arms.* Dated April 15, 1862.

This invention, as far as it applies to revolving and repeating firearms, consists in an improved lock, and in an improved means of fixing and of rotating the revolving chamber, when required for the purpose of firing the charge from one of the compartments, and of locking the chamber when the arm is being carried, and of causing the chamber to rotate after the discharge of one of the compartments, to present another compartment for being discharged. The part of the invention which applies to other firearms, as well as to revolving arms, is the lock. The lock is constructed as follows:—The body of the hammer is centred upon a pin held in the stock; it has a circular aperture made at the back and just above the heel, and to this heel a link is pinned which receives the fore end of the main spring, which is a simple straight blade of steel, the rear end of which is held in a jaw, or otherwise attached to the under part and inside of the stock. The breast of the hammer is formed with two notches for the cock and half-cock; a trigger and trigger spring complete the lock for ordinary firearms. For arms with revolving breech chambers, the following parts are added:—On the near side of the body of the hammer, and at the lower part thereof, a link is screwed, this link is formed with two projecting studs, one on the rear which enters an aperture made for its reception in the body of the hammer, and the other projecting from the opposite side, and fore end enters an eye in the lower end of a paul, the upper end of which takes into the ratchet on the rear of the revolving chamber; at the proper time this rachet comes into action, and drives round the chamber. In the far side of the stock a recess is formed for the reception of a circular spring let into and received to the far side of the body of the hammer. This spring is made with a projecting lip which takes into a notch made in the barrel of a bolt, the fore end of which is thinned off, passes through the shield at the rear of the chamber, and enters one or other of a series of holes made in the rear thereof; a spiral spring is fitted in the recess in the stock and keeps the locking bolt engaged in one or other of the said holes, until forced back by the spring on the body of the hammer engaging in the notch, and when so forced back the chamber is ready for being revolved by the rachet as before described. *Patent completed.*

1082. R. Roche. *An improvement in gun-carriages.* Dated April 15, 1862.

This invention consists in fitting the gun in a block, which is of such length as to receive, not only the trunnions, but also portions of the gun, both in front and in the rear of the trunnions, and in mounting this block in a semi-circular bed on each side of the gun; the sides and bottom of the block are semi-circular, and fit into the bed in such manner, that the block may be moved by worm and worm-wheel, or other suitable mechanical contrivance, so as to elevate and depress the gun according to requirement. *Patent abandoned.*

1083. C. R. Heap. *An improved construction of railway chair.* (A communication.) Dated April 15, 1862.

This railway chair is composed of two wrought-iron plates, one over-lying the other. The under plate is made rectangular, and forms the base of the chair, and the upper plate, which is smaller, lies across it, diagonally, but so that its extremities extend to the end of the base plate. These plates are connected together by a central bolt, which forms a pivot for them to turn on. The central bolt, when the chair is to be fixed in position, passes through a central hole in the plates, and is driven into a wooden sleeper intended to support the chair. The jaws of the chair are formed by turning up portions of the sides of the two plates at right angles. By this means each plate is furnished at its opposite edges with a jaw, which jaws, with the jaws of the other plate, form pairs that are intended to embrace the rail that is to be placed in the chair. Between the jaws of the joint chair and the rail, iron clamping-pieces, rolled so as to fit the web and bottom of the rail, are placed, and the abutting ends of two rails being inserted therein, they will be retained in position. The jaws of the chair are closed upon the clamps, or upon the rail, as the case may be, by turning the upper plate upon its centre, and when brought into position, the grip of the jaw is secured by driving through holes made in the lower plate and into the wooden sleeper below pins or bolts which will bear against the diagonal sides of the upper plate, and effectually prevent that plate from turning. For further securing the rails at their abutting ends, projections are formed on the inner face of the jaws of the joint chair, which projections fit cavities cut in the sides of the foot of the rails, a portion of the clamps being cut away for this purpose. *Patent abandoned.*

1084. A. V. Newton. *Improvements in the manufacture of blasting powder.* (A communication.) Dated April 15, 1862.

The patentee claims, first, the use of nitrate of baryta, obtained in the manner described, or in any other suitable manner, as a substitute (either partial or total) of nitrate of potash in the preparation of blasting powder, in the manner and for the purpose set forth. Secondly, the use, for the manufacture of blasting powder, of the nitrates of strontian and lead as substitutes for saltpetre. *Patent completed.*

1085. G. Bedson. *Improvements in the manufacture of wire ropes, and in the preparation of wire for such manufacture.* Dated April 15, 1862.

This consists, first, in employing flat wire in the manufacture of wire ropes. In straightening wire for wire ropes, the patentee causes it, after it has been rolled, to be wound upon a drum, and between those two points which hold it he cools it, and thus causes a contraction. *Patent completed.*

1086. J. Platt and W. Cheetham. *Improvements in looms for weaving.* Dated April 15, 1862.

This refers to the picking motion of looms, and consists in the adaptation of a spring buffer, or other such elastic apparatus, against which the picking-stick bears when it recedes from the shuttle. Also the patentees apply a similar apparatus for receiving the blow of the picking-stick in its forward motion. *Patent completed.*

1087. J. Platt and W. Richardson. *Improvements in machinery or apparatus for cleaning wool and other hairs of animals from burrs and other foreign matters.* Dated April 15, 1862.

In this arrangement of apparatus the patentees employ a roller, against which is placed a fixed blade, between which and a reciprocating blade, the wool, &c., is introduced. Another feature of the invention is the adaptation of mechanism to the above machinery for opening out the material previously to its being presented to the rollers and blades. For this purpose they adapt a spiked roller or rollers working in a dish, and they employ a transferring comb in conjunction with the spiked roller or rollers and fixed spikes, which draws off the material in detached tufts, and presents it to the said roller and blades. *Patent completed.*

1088. R. A. Peacock. *Improvements in constructing and working lock-gates for docks, harbours, canals, and navigable rivers.* Dated April 15, 1862.

The patentee claims, first, constructing the framing of lock-gates in layers or thicknesses of planking disposed and arranged, as described; secondly, mounting and supporting the weight of lock-gates on pivots or bearings at top, accessible for lubrication or other purposes, as described, and, also, so sustaining the gate as to move with freedom and without any support from the bottom, as described; thirdly, forming mud recesses in the piers at the back of the gates, as and for the purposes described. *Patent completed.*

1089. W. Clark. *Improvements in ornamenting fabrics and other surfaces.* (A communication.) Dated April 15, 1862.

This relates to a method of applying gold or silver leaf, or imitations thereof, to fabrics, &c., by pressure or otherwise, whereby the inventor effects a saving of 50 per cent. in the material beyond that obtained in the ordinary processes. The improvement consists in using the same sheet of metal several times at different parts of the fabric to be ornamented. *Patent abandoned.*

1090. T. W. Gray. *Improvements in the manufacture of explosive compounds.* (A communication.) Dated April 15, 1862.

Here ordinary cotton is used, by preference, cotton being a liguin substance, a compound of carbon (C), hydrogen (H), and oxogen (O), the chemical formula of which, expressed in equivalents, is C 12, H 10, O 10. By subjecting cotton, and most of the liguin substances of the above formula to the action of nitric acid in a peculiar manner, a new element (nitrogen) enters into the composition, forming an explosive compound of the chemical formula, C 12, H 7, N 3, O 22, which may also be expressed $C\,12\left\{\frac{H\,7}{3\ N\,O\,4}\right\}O\,10$. *Patent completed.*

1091. F. C. Philippson. *Improvements in steam hammers.* (A communication.) Dated April 15, 1862,

Here the anvil is made moveable, so that it may be raised or lowered. The bottom of the framing of the machine forms the anvil head, in which are formed two vertical hydraulic cylinders, containing water or oil, and a passage is formed in the anvil head, by which the two cylinders communicate with each other, so that when the ram of one cylinder is raised, the other will be lowered, and *vice versa*. The anvil block is carried on the top of the ram of one of these cylinders. The ram of the other cylinder is of sufficient weight to counterbalance the weight of the ram of the first cylinder, and of the anvil block carried by it. There are other features included in the invention. *Patent completed.*

1092. J. Crossdale. *Certain improvements in boots and shoes, and for ventilating the same.* Dated April 15, 1862.

This refers to a former patent dated 12th April, 1859 (No. 919), and consists in carrying the elastic tubing along the entire length of the in-sole of boots and shoes, the open ends of the said tubes terminating at the heels thereof, and

between the same and the top of the counters of same, instead of carrying the open ends of the tubing up at each side of the waist of the boot or shoe, as described in the specification of the said former patent. *Patent abandoned.*

1093. R. Rains. *Improvements in apparatus for freezing, cooling, and churning.* (A communication.) Dated April 15, 1862.

Hitherto apparatus for freezing, cooling, and churning have been constructed to work horizontally; the apparatus constructed according to this invention is arranged to work vertically. *Patent abandoned.*

1094. S. Barrett. *Improvements in projectiles.* Dated April 16, 1862.

This projectile is formed of cast steel. The end is somewhat smaller than the bore of the cannon, to allow for the coating, and it decreases in size towards its rear end. A lead coating is applied to the projectile, part of which may be inflammable, so as to bring it up to the size of the bore, also, which can be so attached as to follow in its rear after it has been discharged. A series of rings or shoulders are formed in the steel to keep the lead or other material in its place when the projectile is discharged, and until it strikes the object, when a portion will be detached, leaving the inflammable portion still adhering to the projectile. The steel is hollowed from its rear end to about seven-eighths of its length, when a shoulder is formed, and then a smaller bore or hollow is carried to its extremity. In this hollow an iron plug, also with a shoulder, is placed loosely to allow for the escape of compressed air when striking, and when inserted in the hollow of the projectile; the smaller end of the plug projects from the foremost orifice. *Patent abandoned.*

1095. F. W. Gisborne. *Improvements in the construction of electric targets for rifle and gun practice.* Dated April 16, 1862.

In lieu of the chemical decomposition recorder described in the specification of a previous patent, granted to the present inventor on the 16th May, 1861 (No. 1246), he sometimes uses a series of electro-magnets for printing or puncturing the paper diagram, and in order to do so effectually he charges the style points with ink almost simultaneously, and by another arrangement he causes the paper to change its position over the said styles, and thereby record correctly several shots in the same segment. He also uses a disc attached to the target hammers or balls, which moves eccentrically when in motion, and thereby imparts a rubbing electric contact to a spring suitably placed near it. He also combines permanent and electro-magnets to arrest and release at pleasure the balls or hammers when they recoil. He also imparts motion to a slide or shutter in front of the diagram by attaching thereto an iron axis, so placed that, when pivoted eccentrically, it will fly up or back, according to the position of the said axis, to an electro magnet. He also employs the alternate action of electro-magnets, between the target and firing-stand, which in effect are almost synchronous, and in accordance with the meaning of those described of the said former patent. *Patent abandoned.*

1096. T. Edwards and J. Harrison. *Improvements in letter-receiving boxes and other like receptacles.* Dated April 16, 1862.

The patentees claim the construction and use of letter boxes, and other like receptacles, with two or more cut-off flaps or leaves, or their mechanical equivalents, in connection with, and actuated by the opening and closing of a port or cover applied to the opening by which the letters or other articles are inserted into the receptacles, whereby the lower part of the box is divided from the upper portion during the time the cover of the receiving orifice is open. *Patent completed.*

1097. J. Barbour. *Improvements applicable to upholsterers' and other hand hammers.* (A communication.) Dated April 16, 1862.

This consists in magnetising hand hammers, whereby they are rendered available for picking up tacks. *Patent completed.*

1098. W. F. Loc[illegible]. *An elongated projectile to be shot from smooth-bored ordnance, and which shall retain during its flight the longer axis in the direction of its line of flight similarly to elongated projectiles propelled from rifled ordnance.* Dated April 16, 1862.

This projectile consists of a cylinder surmounted by a cone, hemisphere, or other shaped head, forming an elongated shot, the diameter of the case or circular section of the cylindrical part thereof being equal to the calibre of the piece of smooth-bored ordnance for which it is destined with the deduction of the necessary windage; and the axis or length of the projectile will be double the calibre of the piece of ordnance from which it is shot, more or less, as convenient. The projectile retains the direction of its axis or length, after leaving the gun, by means of blades or wings inserted in longitudinal clefts or sockets formed in the cylinder at certain intervals, in greater or less number, and remaining flush with the cylindrical surface of the projectile while in the gun, but projecting from its surface towards the base of the shot after leaving by means of springs, which are relieved by the shot leaving the gun or by other mechanical means. The blades or rings work on rivets or pins towards the front of the projectile, at a greater or less distance from the front of the projectile, the blades or wings extending to the base of the projectile, or short of the base, as may be most convenient, so as by resistance in passing through the air to retain the projectile in its original direction. To prevent windage, and to save concussion, a leaden wad attached to the base of the projectile, or detached, is to be used. The leaden wad is to be placed over the powder with a concave surface towards the powder. *Patent completed.*

1099. J. W. Hadwen. *Improvements in the treatment and application of soft silk waste.* Dated April 16, 1862.

This relates to improved modes of treating the material known as soft silk waste for the purpose of equalising and cleaning the fibre more effectually than has hitherto been done, and consists, 1, In using Heilmann's or other combing machine. 2, In making from the combed silk fibre, when spun, a new fabric suitable for umbrellas and parasols. 3, In mixing the combed fibre with any desired proportion of wool or mohair, and spinning it into yarn. *Patent abandoned.*

1100. D. Stott. *Improvements in the manufacture of rings from paper, millboard, or pasteboard, applicable for steam or other pipe joints, bobbin ends, or other purposes, and in the means or apparatus employed therein, which are also applicable to the manufacture of rings from other flexible substances.* Dated April 16, 1862.

This consists in stamping or cutting out various sizes of rings from one sheet, concentrically to each other, by a series of circular or annular stamps, punches, or cutting instruments, applied or attached to any stamping, punching, or pressing machine of sufficient strength, and actuating a motive power. *Patent completed.*

1101. J. Mackay. *Certain improvements in projectiles for firearms.* Dated April 16, 1862.

This consists in making the bolt in the form of a hollow cylinder or tube, the end next the powder being closed with a plate which detaches itself upon leaving the barrel, the barrel through the bolt being then left open for the passage of the current of air, which maintains the true position of the bolt as it progresses, thus ensuring the proper part of the bolt to strike the object. This form of bolt will also penetrate iron or wood more readily than solid projectiles. *Patent completed.*

1102. J. M. Rowan. *Improvements in manufacturing articles of cast steel.* Dated April 16, 1862.

This consists in applying pressure, by hydraulic apparatus, for examples to the cast steel in the moulds when in a fluid or nearly fluid condition. *Patent abandoned.*

1103. R. Cochran, and R. Cochran, jun. *Improvements in producing ornamental fabrics.* Dated April 16, 1862.

Here the object is for the production, in a novel and economical manner, of ornamental fabrics of the many coloured harness woven kind, such as bordered shawls, long shawls, or plaids, &c. And in practising the invention after one modification, supposing the article to be produced is a shawl having a self-coloured or plain centre with a border, the inner edge of which has an ornamental outline projecting unequally into the plain centre part, such border is woven separately, and being cut along the inner unequal line, is neatly stitched upon a plain or self-coloured piece of cloth. *Patent abandoned.*

1104. F. P. Warren. *Improvements in apparatus for steering sea-going vessels.* Dated April 16, 1862.

The object here is to enable sea-going vessels to be steered with greater accuracy and facility than at present; as, also, when two rudders are used, in case of accident to the ordinary rudder, to afford a means of steering the vessel independently of it. For these purposes the patentee makes use of a metallic or other rudder, situated at the forward part of the vessel, in some cases placed in a recess or opening formed in the forward "dead wood," or equivalent metal of the vessel; in others, carried by a false stem, additional to and projecting in front of the real one, the rod pintles or other axis or axes, upon or about which the rudder turns, being in each case situated at the forward side of the rudder itself. A rudder situated and hung as described, has the advantage of meeting and being acted upon directly by the solid water opposed to the forward motion of the vessel, instead of acting only against the inferior resistance offered by the more or less broken water at or about the stern. *Patent completed.*

1105. M. Cartwright. *Improvements in the manufacture of models, and of plates or pieces for artificial teeth, and in combining or amalgamating india-rubber and gutta percha with metals for the manufacture of artificial plates or pieces, and for other purposes.* Dated April 16, 1862.

This consists in a method of making models used in preparing plates or pieces for artificial teeth of vulcanite, ebonite, or hardened rubber, alone or in combination with soft vulcanised rubber. The invention also consists in a method of combining or amalgamating india-rubber and gutta percha with metals for the manufacture of artificial plates or pieces, and for other purposes. *Patent abandoned.*

1106. W. J. Marsden. *Improvements in eye shades.* Dated April 16, 1862.

These eye-shades are formed of silk, cotton, alpaca, gossamer, muslin, linen, or other light material sewn or fastened to a wire framework, consisting of two, three, or more curvulinear wires, the smallest of which adjusts itself to the forehead, and the others projecting so as to form a protecting shade set at the desired angle to the rays of light. The extremities of these curvulinear wires are jointed by vertical hinges to the ear pieces, which are similar to those of spectacles, by the intervention of short pieces of metal jointed at their opposite ends by a horizontal hinge to the spring wires which pass over the ears. The vertical hinges allow the ear pieces to be folded over the front and upper part of the shade, and the horizontal hinges allow of the lateral adjustment of the spring wires. The curvulinear wires of the frame of the shade are easily adjusted so as to cause the shade to project horizontally, or to descend and form a peak, as may be desired. *Patent abandoned.*

1107. W. E. Newton. *An improvement in setting artificial teeth.* (A communication.) Dated April 16, 1862.

This consists in a certain mode of combining the teeth with a gold platinium, or other metallic plate, by means of india-rubber or other vulcanised gum, whereby all soldering and rivetting, by which the plate is liable to be warped, is dispensed with. The metal is also prevented from oxidying, and the gum when vulcanised is made to serve as a means of strengthening and preserving the form of the plate. *Patent completed.*

1108. W. E. Newton. *Improvements in the manufacture of cannon and other ordnance, and of solid and hollow cylinders for shafting and other purposes of wrought-iron, or steel, or both combined.* (A communication.) Dated April 16, 1862.

One of the improved modes of constructing cannon and other ordnance, and shafting or cylinder, which form the subject of the present invention, consists in rolling or winding a plate or sheet of iron, or steel, or several (if more than one is required), around a central mandril of wrought-iron, steel, or other suitable material. The whole mass is then to be heated to a welding heat, and welded together as it is rolled up. The welding operation is to be effected either by the pressure of rollers, or by the impact of a hammer or hammers, while the metal is at a welding heat. If a gun or piece of ordnance is to be produced, the mandril should be of less diameter than the desired bore of the gun or cylinder of the latter, is intended to be hollow, so that the boring operation will remove all of the mandril. *Patent completed.*

1109. J. Stanton. *Improvements in apparatus or machinery to be used in stamping or piercing metal washers and other similar articles.* Dated April 16, 1862.

Here the patentee uses a machine consisting of two punches and their bolsters, the one set at an angle of about 60 deg. with the other, bent in gear with each other. The metal having been supplied to the first punch, a blank is struck out, and this blank falls through an aperture in the bolster, which aperture is provided on one side with an inclined plane of stout glass, or other suitable material, which throws the blank to the bottom of a receiver below the bolster. In this position the blank is caught by a grip or catch, which retains it whilst the second punch perforates the blank. Upon the grip or catch receding, the washer falls out of the machine completed at one operation. The two punches may be geared together to work reciprocally by a connecting rod and lever, or in any other suitable manner. *Patent completed.*

1110. J. H. Johnson. *Improvements in machinery or apparatus for cutting the teeth of wheels, racks, or segments.* (A communication). Dated April 16, 1862.

This consists in the use of a cutter in the form of an endless screw, made adjustable to any desired angle, and composed of hardened steel, and having its surfaces file cut, or formed with cutting edges, so as to be capable of cutting or reducing metals. *Patent completed.*

1111. J. Ashbury. *Improvements in the permanent way of railways.* Dated April 16, 1862.

Here it is proposed to use a rail having the ordinary bearing flange at its upper surface, but with a slightly tapered or wedge-shaped web in transverse, the narrowest portion of the rail being at its lower edge. This rail is dropped into a chair, the inner surfaces of the jaws of which are made to approach each other towards the lower portion of the chair, thus presenting a tapered or wedge-shaped opening or trough for the reception of the corresponding tapered web of the rail, which fits it accurately at the sides. Any heavy weight passing over the rail will tend to force it down into its chair, and will, consequently, still further tighten it therein without the necessity for keys or wedges of any kind. If desired, a small wooden bearing piece may be inserted into the bottom of the chair to receive the direct pressure of the rail, but this may be dispensed with if preferred. The rails may be prevented from arising from their chairs by pins or bolts passing transversely through the rail and jaws of the chair, a ring or cutter serving to prevent the accidental displacement of the bolt; but in some cases these bolts or pins may be dispensed with. The joint chairs are made like the intermediate chains, but wider, and the bolt or pin is passed tnrough the two jaws and through an opening made between the rail ends, so that one bolt will serve to hold down both rail ends. It is preferred to form these chairs by rolling them from wrought-iron plates, but they may also be made of cast-iron if desired. *Patent completed.*

1112. J. H. Johnson. *Improvements in railway and common road carriages.* (A communication.) Dated April 16, 1862.

This relates to a peculiar mode of mounting railway and common road carriages upon their running wheels, and consists in mounting such vehicles upon wheels, rollers, or cylinders which rest at their peripheries upon the ordinary axles of the vehicle. The axles of the upper and lower wheels are by this system considerably reduced in diameter, and hence the friction is reduced, and a considerable saving of tractive power is obtained. The upper wheels are mounted in forked guide irons, which take the entire weight of the load, suitable springs being adapted thereto. The axles of the upper and lower wheels may be allowed to work freely within slots or springs made in the forked guide irons, and in some cases one or both of the lower wheels may be loose on their axle to facilitate turning or the passing over curves. *Patent abandoned.*

1113. J. W. Ford. *Improvements in sewing machines.* (A communication.) Dated April 16, 1862.

We cannot here give space to the voluminous details of this invention. *Patent completed.*

1114. J. Weston. *Improvements in machinery for morticing, drilling, and dove-tailing, and in tools to be used therewith.* Dated April 16, 1862.

We cannot here quote the details of this invention. *Patent abandoned.*

1115. C. D. Abel. *Improvements in the manufacture and production of the chromates and the bichromates of potash and of soda.* (A communication.) Dated April 17, 1862.

This consists in substituting sulphate of potash and sulphate of soda for the carbonates and nitrates of these bases as used at present in the manufacture, respectively, of the bichromate of potash and of the bichromate of soda. *Patent abandoned.*

1116. A. Krupp. *Certain improvements in the manufacture of screw propellers.* Dated April 17, 1862.

This consists in forming screw propellers in one piece, or in two or more pieces, from a solid block or blocks of cast steel, and forging the said block or blocks into the necessary shapes. Where it is desirable, for convenience or economy, to form the propeller in two or more pieces, the inventor forges the pieces from solid blocks of cast steel, and fits them together. *Patent abandoned.*

1117. V. Fleury. *Improvements in clocks and other timekeepers.* Dated April 17, 1862.

This consists in the construction of a novel escapement, which may be adapted to the usual clockwork. *Patent abandoned.*

1118. W. H. Hutchinson. *Improvements in the manufacture of ammonia, or its salts and cyanogen, or its compounds from refuse gluten.* Dated April 17, 1862.

In carrying out this invention, the refuse gluten from starch or other manufactures is subjected to destructive distillation in iron, clay, or other suitable retorts, and the gaseous products are condensed or collected in any way. From these products the pure ammonia is obtained by filtering and redistillation, or is crystallized by the addition of acids. The inventor obtains the compounds of cyanogen either by fusing the refuse gluten in a retort with potash, soda, lime, or other salts, or by passing the gaseous products from the first retort over red-hot charcoal, soaked beforehand in a solution of the required salt or salts. *Patent abandoned.*

1119. J. Griffiths. *Improvements in propelling ships and other navigable vessels.* Dated April 17, 1862.

This relates to that system of propelling by water where motive power, steam, or other engines are employed to work pumps or propelling cylinders, which take in and force out water. Thus the liners of the said ships or other navigable vessels, such water being ejected under the water line, at an angle or a direction towards the bow or stem, causing a vessel to move in the opposite direction to the ejected current ahead, astern, or otherwise, as desired. The pumps may be single or double acting, and are placed by preference athwart ship alongside acting engines in or about that part of the vessel deepest in the water. To each of the said pumps, if single acting, are two communications by tubes with the water outside the vessel, the terminations of which are made to direct the water taken in by the action of the pumps or propelling cylinders, and displacement of the vessel downwards and at an angle to the keel. In the tubes above named, or in or about the tubes or pumps, parts, or the whole of which may be covered with water, confined in a tight compartment, are throttle or other valves, so placed, and under the control of the engineer, that, by moving the necessary levers, he can alter or reverse the course of a ship without stopping or reversing the engines. *Patent abandoned.*

1120. W. Harling, J. M. Todd, and T. Harling. *Improvements in looms for weaving.* Dated April 17, 1862.

This relates to an improved brake and stopping motion, and consists in fixing the frog to a shaft, so that it may slightly turn or oscillate on a bearing, instead of sliding on the loom side as at present. To the shaft to which the frog is attached, there is a double or two-armed lever, having one arm shorter than the other. To the short arm is connected one end of the brake rod, the other end of which is curved to suit the fly wheel, and mounted with wood or leather in the usual way. The top of the long arm of the aforesaid lever acts upon the stopping handle or setting on rod, and, in consequence of its increased length, acts sooner upon the strap than upon the brake, and the strap is shifted to the loose pulley before the brake is in contact with the fly wheel. The brake rod is placed in an inclined position, so that by its own weight the brake may fall back from the fly wheel when the stop rod finger is not acting against the frog, and thereby prevent any possibility of the brake being in contact with the fly wheel until required. When desirable the patentee uses an oscillating frog, and also a stop rod finger, at each end of the loom, instead of at one end only; but in either case the stop rod finger and frog are placed in a direct line with the sword arm, and thereby prevent side strain or injuries. *Patent completed.*

1121. F. Tolhausen. *An improved machine for making bricks, tiles, and the like articles.* (A communication.) Dated April 17, 1862.

This consists of a strong metallic disc turning on a central pivot, and supported on its rotatory motion by castors or spherical balls that are arranged round the circumference like in a railway turn-table. There is a suitable number of moulds fixed all round on the disc, and the said moulds having been filled with the material in the ordinary way the disc is made to turn so as to bring the moulds successively under the action of one or several shaping or pressing plates that are arranged around and above the rim of the disc. The said pressing and shaping plates are acted upon by a screw and fly wheel, in the manner of a fly press. The disc may be moved by one or more fly wheels set tangentially in a vertical position, and acting either by friction or bevil gear. The said fly wheels by cams also act on plates for lifting the brick or other article out of the mould in which it has been compressed and shaped by the plates, as above described. *Patent abandoned.*

1122. J. Murphy, sen. *Improvements in looms.* Dated April 17, 1862.

This consists in applying to looms a floating race, to admit of two shuttles being actuated simultaneously. *Patent completed.*

1123. J. P. Temberley. *Improvements in the air-pumps of steam engines.* Dated April 17, 1862.

This consists in fitting a plunger or ram upon the piston-rod of the air-pump cylinders of condensing engines, or in otherwise connecting a plunger with the ordinary bucket. By this means, the action of the air-pump is increased, and a portion of its work performed during the down stroke, whereby the size of the air-pump may be reduced accordingly. *Patent abandoned.*

1124. G. T. Bousfield. *Improvements in sewing machines.* (A communication.) Dated April 17, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1125. J. L. Perin. *Improvements in machinery for mortising wood.* Dated April 17, 1862.

This consists in the use of a rose drill or fraise, to which the patentee imparts three self-acting motions: the first, a rapid rotary motion, for cutting away the wood; the second, a to and fro movement, which is determined by the length of the mortise to be cut; and the third, a penetrating motion, according to the depth of the mortise to be cut. The two latter motions, if necessary, can, however, be imparted by hand. The timber operated on remains stationary during the triple action of the drill. In order to square out a mortise hole thus obtained, he makes use of a right-angled tool, which is impelled by hand. He also attaches to the machine embodying the improvements in drilling machinery to pierce round holes preparatory to mortising, or for other purposes, if necessary. *Patent completed.*

1126. H. Gardner. *Improvements in machinery for breaking and preparing flax and other fibrous substances.* Dated April 17, 1862.

This consists in the combination of three plated rollers mounted in a suitable frame, one of such rollers in the front of the machine being mounted in elastic bearings, and the other two rollers being mounted in fixed or inelastic bearings. The material intended to be operated upon is fed into the machine on the upper side of the front roller, and is drawn in between it and the upper, whence it passes between the lower part of the said front roller and the lower roller, and is delivered on to a table or other receptacle in the front of the machine. The bearings of the front or feeding roller are rendered elastic by means of a spring fixed at each end of its axis, the elastic power of the springs applied thereto being varied to suit the particular material intended to be operated upon. The power, whether manual or mechanical, is applied either to the axis of the upper roller, or to that of the lower roller. *Patent abandoned.*

1127. C. D. Abel. *Improvements in the manufacture and production of certain alloys, containing cadmium.* (A communication.) Dated April 17, 1862.

This consists in the formation of alloys of gold, silver, and copper with cadmium. The alloys of silver, copper, and cadmium, besides being useful for various other purposes, are particularly adapted for forming into wire by drawing on account of their great ductility. The alloys of gold, copper, and cadmium are applicable to the manufacture of wire by drawing, and to jewellery generally. *Patent completed.*

1128. R. A. Brooman. *Improvements in taps and valves.* (A communication.) Dated April 17, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1129. R. A. Brooman. *Improvements in buffing apparatus and in drawing springs.* (A communication.) Dated April 17, 1862.

This invention consists in the employment of wedge-shaped blocks, connected to the buffer heads through their rods and a cross bar, or otherwise, and to the draw rods, which wedge-shaped blocks are pressed upon by springs directly, or by jaws acted upon by springs, in order that the ends of the springs or of the jaws may be kept in contact with the sides of the wedge-shaped blocks. There are various means of applying this invention, for instance—1st. A wedge or wedge-shaped block may be fixed on the back of the buffer head, and two rods or jaws may be fitted under the carriages, with the division between the two outer ends of such jaw, opposite or in a line with the point of the wedge, and with springs pressing upon the jaws, and exerting their force to keep the jaws closed until overcome by the superior pressure applied upon the buffer heads, when the wedge will gradually force the jaws apart. In some cases the wedge may be in the form of a spear head, and studs may be applied on the inner ends of the jaws in order to enter behind the spear head, and prevent the back action of the springs—a source of mischief in cases of collision from buffer apparatus as now generally constructed. 2nd. For some purposes, instead of having two buffer heads and appurtenances at the end of each carriage, the inventor sometimes employs only one buffer head, extending across the end of the carriage frame, and fits one wedge or wedge-shaped block at the back and in the centre thereof. He then only employs one set of jaws and springs. Again, he forms draw springs by applying at the back of the draw hook a similar wedge or wedge-block and jaws and springs, but in such case the point of the wedge is placed in the reverse direction. Sometimes he combines both draw spring and buffer apparatus in one by the employment of a double wedge or double wedge-shaped block, with a set of jaws and springs for each wedge or block. Again, he sometimes makes one set of springs act upon the buffers and draw hooks at both ends of the carriage. He connects the inner ends of the buffer rods at each end of the carriage to a cross bar, through the centre of which the draw rods pass, and he connects each of such cross bars and draw rods to a double wedge block. He then fixes two strong elliptical plate springs in such a position that the ends thereof shall enter the narrow parts of the two double wedge-blocks, and exert their pressure thereon. Thus, whether the draw hooks be drawn outwards, or the buffers be pressed inwards, the springs exert their whole pressure and prevent any evil effects and shocks, whether from the pull of the draw hooks or the thrust of the buffers. *Patent completed.*

1130. W. Anderson. *Improvements in tubular steam generators.* Dated April 17, 1862.

This consists in the means resorted to for fixing the bends which connect the ends of the tubes to each other. The tubular bends are each made with sockets to receive the ends of the tubes to each other. The ends of the tubes pass through iron plates, and the connecting of the ends of the tubes is external of the two end plates. The above description of steam generator is not new, but in place of fixing the connecting bends as heretofore, they are, by this invention, fixed by means of studs or rods with screwed ends, such studs or short rods being fixed to the plates, through which the ends of the tubes pass. *Patent abandoned.*

1131. H. Gallagher. *Improvements in overalls, leggings, or in overboots, which he intends to name "Gallagher's patent Ecreece."* Dated April 17, 1862.

This invention consists in constructing a boot of such dimensions that it shall be readily drawn on over the ordinary shoes or boots and trowsers, or leg and foot when dressed in the ordinary garments. And this boot the inventor makes with a sole of a peculiar character, it having, in fact, no sole beneath the "ball" part of the foot; and he prefers to make the toe-part of steel or iron, and the "waist" much lighter than in ordinary boots and shoes. Also to some height from the ankle a cut is made, and an elastic side-spring inserted with the view to facilitate the overboot being pulled on and off, and held firmly in position on the leg when in use. *Patent abandoned.*

1132. S. Rideal and R. Shepherd. *Improvements in railway-break apparatus.* Dated April 17, 1862.

The patentees claim the application of rods or bars moved longitudinally for the purpose of effecting communication throughout the several bars fitted to a train of carriages, and acting on the brakes as and for the purposes described, *Patent completed.*

1133. W. Clark. *Improvements in the manufacture of railway rails.* (A communication.) Dated April 17, 1862.

The patentee claims the improved methods for the acieration or mixed cementation of the upper parts of the casings of rails, which constitute the principal face of the rails. These new methods consist in protecting the said rails by coverings of sheet iron, or by the simple contact of the casings of the rail at certain parts of the surfaces, as described, instead of using argilatcions, or silicious earths, or slag, as in ordinary. *Patent completed.*

1134. J. C. Rivett and J. M. Hetherington. *Improvements in machinery or apparatus for preparing cotton and other fibrous materials for spinning.* Dated April 17, 1862.

This invention refers to the carding engine of that construction for which letters patent were granted to the above mentioned J. C. Rivett, dated 13th April, 1861 (No. 906), and consists, firstly, in an arrangement for causing the backward and forward motion of the rollers described in the specification of the said patent. For this purpose the patentees employ a worm and worm wheel, the former of which being caused to vibrate bodily, acts as a check, and causes the latter to turn upon its centre, so as to communicate motion to the rollers in both directions, and then the vibrating motion brings a click to act against a ratchet-wheel upon the axis of the said worm, whereby it is caused to revolve for effecting a necessary gain in the revolution of the rollers. Another improvement relates to the changes to be effected in the said description of carding engines, viz., firstly, traversing the strap to stop the feed. Secondly, Bringing the brush into action by reversing the cylinder. Thirdly, The starting again all these changes now derived from the loose pulley, and adapting a line shaft with cams thereon for the said purposes. Another improvement consists in forming the cleaning brush with rings, and in traversing it between each change, so that it acts upon a portion only of the cylinder at a time. Another improvement relates to the combs used in conjunction with the rollers as described in the specification of the aforesaid patent. These combs are stationary, but the patentees propose to traverse them in the direction of the axis of the said rollers, or to bring them into contact occasionally only. Another improvement also relates to these combs, and consists in using a portion only thereof when desired, and they therefore adapt them so that they may be readily removed. *Patent completed.*

1135. R. Wedgwood. *Improved apparatus for facilitating the saving of life in cases of fire.* Dated April 17, 1862.

This invention consists of a series of light or hollow rods, made of bamboo cane, metal tubes, or other light and strong material. These tubes or rods are provided at one of their ends with sockets, in which the ends of the other tubes are inserted, so as to form a rod of considerable length like a jointed fishing-rod. The topmost joint of this rod is provided with a hook or ring, on to which may be hung a small pulley with a cord, which may be thereby conveyed up to the persons in the upper floors of the house, and by means of this cord a basket, car, box, or other analogous contrivance, may be conveyed up to the persons in danger, who will then be able either to descend, or, by means of apparatus conveyed up to them, to assist in putting out the fire. *Patent completed.*

1136. R. Dennison. *Improvements in reaping and mowing machines.* Dated April 19, 1862.

This invention consists in the employment of shear-cutters arranged in alternate series upon and fixed to two laterally sliding bars or carrier frames, placed one above the other, the reciprocating lateral motion of the said bars to which the shear blades are fixed or hinged giving the requisite cutting motion thereto. *Patent completed.*

1137. E. Dove. *Improvements in matches and fusees, and apparatus for containing and igniting the same.* Dated April 19, 1862.

The matches or fusces are, according to this invention, made on one continuous strip or band, which is coiled up on a centre or small portion of wood or other material, and is inserted in a box or case of any shape or size, either for the pocket or otherwise. The outer end of this band is passed through an opening in the periphery of the case or other part thereof, and when drawn out through the opening it there comes in contact and passes under, over, or through one or more roughened or pointed igniting surfaces, which may be either a spring or otherwise, and in thus passing the composition with which each match is charged, becomes ignited, burning off, and leaving in the brand a sufficient length of match or fusee, and a sufficient portion protruding from the box or case by which the succeeding match may be likewise drawn out. *Patent abandoned.*

1138. J. S. Phillips. *A new method and apparatus for the propulsion of vessels through the water.* Dated April 19, 1862.

This invention consists in constructing wheels for the propulsion of vessels through the water with floats or propellers of a form resembling the hoof of a calf, or the foot of a cormorant, when that bird is propelling itself through the water. The number of propellers or floats that are applied to each wheel may be varied, but the patentee believes that, ordinarily, seven will be found a very convenient number. *Patent completed.*

1139. J. Shanks. *Improvements in apparatus for promoting ventilation, also applicable to drying stoves.* Dated April 19, 1862.

In practically carrying out this invention, in the case of a room or building, for example, separate tubes or passages are provided for the inlet and outlet currents, such tubes

being placed as far apart as is convenient. The inner opening of each outlet tube is in or near the ceiling or roof of the room or enclosed space, and the tube is carried up to a height that its top end is considerably above the level at which it is convenient to have the top of the inlet tube or tubes. The inner opening of each inlet tube may be at any convenient or desired level in the room or enclosed space, excepting above the level of the outlet openings. When the temperature within is from any cause slightly raised, there is a warm and consequently light column of air in the elongated outlet tube, which is counterbalanced by the colder and heavier air in and above the inlet tube, and the latter descends and a current is thereby established. *Patent abandoned.*

1140. M. MASTERS. *Improvements in artificial legs.* Dated April 19, 1862.

This invention consists of an improved hinge or joint for artificial legs. It is made of metal, or other suitable material, and instead of being solid, as at present, it has a hole or perforation in the centre, or at the part corresponding with the condyle or bone at the inside of the knee. Each joint is made of large diameter for the purpose of obtaining strength and steadiness, and the two shoulders and internal part of the joint are kept together by turning or hammering over the ends of a short tube into countersinks formed at the edges of the holes in the shoulders. *Patent abandoned.*

1141. R. and J. STUART, and H. HILL. *Improvements in fastening flyers upon spindles.* Dated April 19, 1862.

This invention consists in forming a deep spiral groove in the top or head of the spindle, whether the top or head be made tapered or not, and whether with or without a shoulder, and in fixing inside the tube, from which the flyer legs extend, a stud or projection to enter the groove in the spindle top or head. The patentees sometimes make a different shaped groove, but in all cases of such shape, that, by being taken into by a pin or stud inside the flyer tube, a sufficiently secure fastening is made to keep the flyer on the spindle. Sometimes they reverse the groove and stud, that is, they make the groove in the flyer tube, and form the pin or projection in the spindle top or head. The great advantages arising from the means of fastening above described, consist in the facility thereby afforded of "doffing," or taking off and replacing the flyers, and the time saved in that operation as compared with the ordinary means of fastening. *Patent completed.*

1142. B. RHODES. *Improvements in the machinery for, and in the method of, making, also in the materials to be employed in the manufacture of cylinders, tubes, and other vessels from paper and other materials or fabrics.* Dated April 19, 1862.

We cannot here give space to the voluminous details of this invention. *Patent completed.*

1143. W. MUNN and D. BALLANTINE. *Improvements in mills for grinding.* Dated April 19, 1862.

Under one modification or form of arrangement, the mill is supported on a framing of cast-iron, forming a table on which the hopper and grinding apparatus is arranged. At the lower part of the framing, and extending across it, is fitted a horizontal stay piece, which forms a footstep bearing for a central vertical shaft. This shaft passes up through the centre of the table, and its upper extremity revolves in a collar bearing fitted in the lower part of the hopper, the shaft passing through a box within which the grinding discs are arranged horizontally, and rotating one above the other; they are by preference formed of iron, with radial or other grooves in the working faces. The upper disc is fast to the central shaft, and the lower disc is carried on a tubular shaft which works outside the other. The central shaft is provided with the means of adjusting the distance of the discs one from another. This is done by means of a screw fitted at the lower end for raising or lowering the shaft. Motion is given to the main shaft from a driving shaft actuated either by hand or power; near the inner end of this shaft is fitted a bevel spur-wheel, which gives motion to a pinion on the vertical shaft. On the extremity of the driving shaft, and inside the main spur-wheel, is a second bevel-wheel which actuates the tubular shaft carrying the other grinding disc. It is preferred to actuate this disc at a lower speed than the upper one, and, when required, the shaft may be readily thrown out of gear by sliding the pinion up the feather formed on the tubular shaft. The materials to be ground are fed in through the hopper in the usual way, and pass down between the grinding discs, where they are subjected with more or less severity to the triturating action, according to the adjustment of the discs, which is suited to the material under operation. *Patent abandoned.*

1144. B. BROWNE. *Improvements in breech-loading fire-arms.* (A communication.) Dated April 19, 1862.

In carrying out this invention the inventor forms the outside of the breech end of the barrel enlarged, and chambers such part out, leaving a long opening at top into which a hollow piece of metal is fitted and connected to the barrel by a pin or screw; the upper side of this hollow piece of metal is fitted with a nipple, which is placed in a line with the centre of the barrel; a swell or projecting flange surrounds the said nipple, and serves to raise the aforesaid hollow piece out of the barrel for inserting the cartridge therein; the aforesaid, flange is extended so as to cover the openings between the sides and end of the chamber and hollow piece aforesaid, when inserted therein, the said hollow piece being locked to the barrel by a spring bolt taking into a hook fixed to the under side of the hollow piece aforesaid near the front thereof. In connection with the aforesaid spring bolt is a trigger which protrudes slightly through a slit in the under side of the stock of the gun in front of the ordinary trigger; a spring is also adapted to the under side of the before-mentioned hollow piece to assist in raising the same when the spring bolt has been withdrawn therefrom by the trigger thereof. *Patent abandoned.*

1145. E. LOYSEL. *Improvements in locks and fastenings.* Dated April 19, 1862.

In some of the locks described in the specification of a former patent, dated 17th July, 1860 (No. 1731), two, three, or more, divided cylinders were employed, and in the ends of these cylinders were made holes to receive a series of pins, on the face of a circular plate attached to the central spindle. A number of false notches, or holes, as well as the proper notches to receive the pins, were made for the purpose of deceiving any person who attempted to pick the lock. It has been found, by experience, that a skilful person can, with care, discover (by feeling) where the pins should be placed, and need not be very greatly deceived by the false notches. The object of the present invention is to obviate this objection, and to give unqualified security to the lock, so as to render it impossible, by merely feeling, to place the parts in their proper position. By the first improvement the patentee is enabled to dispense with the false notches or holes on the cylinder, and he adapts to the latter sets of pins, which correspond with holes made in two circular plates, one of which may be rotated, while the other is secured to the central spindle and other parts in such manner that it cannot rotate, but will remain stationary until the spindle is drawn back. Another improvement consists in dispensing with the pins on the spindle plate, and employing, in combination with the latter, a rotating plate, in both of which plates coincident holes are made to receive the pins of the cylinders. In the former invention the pins on the spindle-plate were of different lengths, depending upon the position of the cylinders; but in the improved lock, all the pins of all the cylinders are made with their outer ends in exactly the same level, so that their position, in reference to the holes in the circular plates, cannot be felt or known until all the pins of all the cylinders are brought into the proper position for unlocking the bolt. The rotating plate in which the holes are made is actuated by means of a pin fixed in either of the cylinders, and this plate is placed within the flush pins and the holes, so that, until the holes in both plates are brought into coincidence, the pins cannot be inserted. These locks may be adapted to various purposes, either for safes, drawers, and portmanteaus or bags, where security is required. *Patent completed.*

1146. W. ROSE. *Improvements in the manufacture of tubes, more especially applicable to the barrels of firearms and ordnance.* Dated April 19, 1862.

In carrying out this invention, with reference to the making of barrels of firearms and ordnance, the patentee takes a strip, band, or skeep of iron or steel, or a mixture of both, and passes it through grooves to the requisite section in a train of rolls, or through dies on a draw-bench, by which operation the metal is turned up into a form nearly approaching a complete tube; or it may be completely formed into a tube, and securely welded by the rolling process, or in the dies if necessary. He then cuts this tube, or partial tube, into lengths suitable for the purpose, for which the barrel may be ultimately intended, which, for a small arm, such as a rifle, would be about 1 ft. each length. Upon each of these short tubes he proceeds to twist a band or bands, strips, or ribands of iron or steel, or both combined, forming such bands into a rough coil upon the inner lining tube. He then heats the whole mass, and takes it from the furnace upon a stop mandril, and jump it, if necessary, to close the coil. He then takes it, at a welding heat, upon an ordinary roller mandril, to a train of ordinary gun rolls, passing it through the grooves in such rolls once, twice, or three times, as may be requisite, the use of the mandril and the rolls insuring internal as well as external pressure. By this process the tube is drawn out, and each coil of the twist is securely welded upon the inner lining tube, and also edge to edge upon its adjoining coil, and in its last passage through the rolls by employing temporary common barrel rollers or tapering mandrils, the necessary taper required in a small arm barrel or piece of ordnance is given to the tube. Should one band or coil upon the inner lining tube afford insufficient thickness for the barrel, he coils back upon the former more bands, until a sufficient thickness of metal has been insured. This operation is, of course, performed before beating or welding the mass together. In making ordnanse and heavy guns, he employs the same process, but with more material and suitable mechanical appliances for dealing with heavier weights. After having coiled the strip or bands upon the inner or lining tube, he heats the mass, and, if necessary, removes it upon a stop mandril to what is known in the trade as a jumping machine, in which, under heavy blows from a forge or steam hammer, or other suitable apparatus, the coil is closed up edgeways. He then reheats it, and takes it upon a mandril to the rolls, which, for this purpose, require to be of a very strong description. By passing through the grooves of the rolls the coil or coils are welded firmly on the tube by the internal and external pressure. In the manufacture of tubes other than those employed for firearms or ordnance, he adopts the same process already described, omitting the taper rolling, unless taper tubes are required. Tubes may also be made by this process of other metals than iron or steel, and for other purposes than the barrels of firearms or ordnance, provided the metal be capable of being welded or united by heat. *Patent completed.*

1147. A. PARKES. *Improvements in the manufacture of rollers for surface printing and embossing.* Dated April 19, 1862.

Here the patentee casts the liner or inner roller hollow interiorly, so that it then fits the mandril only at each end, or, if greater strength is required, a central bearing surface may also be provided. He makes the liner of cast iron, or, preferably, of cast steel. At the places where the liner fits upon the mandril, he in some cases bushes it by preference with copper or brass. He secures the roller on the mandril by a solid nib or projection left on the side of the hole through which the mandril passes; this nib enters a recess or key way cut for it in the axis. When the liner is bushed with copper or brass, the nibbing may be effected by a machine similar to that commonly used in nibbing copper rollers; but when the liners are not so bushed, he forms the nib by a machine of which the cutting tool rises and falls vertically in the manner of a slotting machine, as the machine ordinarily used for nibbing copper rollers will not cut iron efficiently. *Patent completed.*

1148. A. W. WORNUM. *Improvements in pianofortes.* Dated April 19, 1862.

Horizontal pianofortes are usually considered to be, in many respects, preferable to upright pianofortes, but they have the disadvantage of occupying a much larger space. Now, according to this invention the patentee furnishes a horizontal instrument with axes or trunnions about which it is balanced. The frame receives these axes or trunnions in suitable bearings, and it is so constructed, that the instrument may be turned about on its trunnions, either to bring it into a horizontal position for use, or to place it in a vertical position, so that when out of use it may occupy even less space than an ordinary upright instrument. The invention also consists in an improvement on the horizontal pianoforte action, described in the specification of a former patent granted to the present patentee, dated 11th July, 1856 (No. 1,644). In this action the key gives motion to one arm of a bell crank lever, to the other arm of which the fly or hopper—which acts on the hammer butt, and actuates the hammer—is jointed; the damper is actuated by a rod passing from the extremity of the arm of the bell crank lever which carries the fly over and above the hammer, to another bell crank lever carrying the damper, which is thus actuated. The present improvement consists in bringing the damper action between the hammer and the string, which he is able to do by attaching a projecting piece to the bell crank lever, which is actuated by the key; this projecting piece is carried by the under side of the arm thereof, on which the key acts, and when the key is depressed it comes in contact with another projecting piece on a straight bar mounted on a centre at one end, and carrying the damper at the other; the projecting piece on this lever being acted on as above described, causes the lever to turn on its centre and the damper to be raised. *Patent completed,*

1149. A. PARKES. *Improvements in surface condensers.* Dated April 19, 1862.

This consists in coating the tubes with silver by an electro-plating process. The tubes may, with advantage, be silvered both inside and out; the principal advantage, however, is, the patentee considers, obtained by silvering the surface with which the steam comes in contact. In plating the tubes the patentee employs the ordinary electro-plating process, a silver bath to receive the tubes being made use of. He prefers to use a coating of silver equal to from 30 to 40 grains per square foot of surface. *Patent completed.*

1150. H. LUMLEY. *An improved rudder.* Dated April 19, 1862.

Here the patentee constructs a rudder in two moveable portions, connected together edgewise, the outer or further portion, which he calls the "tail," being at the outer end of the inner or hither portion, which he calls the "body," the two portions are hinged-jointed, so that, when the body is moved, turned, or worked to steer the ship or vessel, the tail also turns or works at the end of the body, and assumes various angles with respect thereto. *Patent completed.*

1151. A. P. TROUCHOW. *An improved construction of houses, murals, mobil palisades, fruit walls, and other analogous objects.* Dated April 21, 1862.

This consists in forming the pieces of the framework of houses of wood, cast or forged iron, and the parts which are to be full with an iron wire lattice or trellice, and also of wood, in certain cases covered with plaster or other suitable material; the parts representing the walls are double, with a space between them to form the thickness of the walls. These spaces may be filled with sand or other materials, or with the earth dug up for forming the foundation or cellars. The partitions may be made of single trellis, without forming two thicknesses. The uprights composing the framework support the parts forming the floors composed of iron lattice, which, being coated with plaster, forms the ceilings. *Patent completed.*

1152. J. COMBE. *Improvements in machinery for hackling flax and other fibrous substances.* Dated April 21, 1862.

This relates to an improved arrangement for connecting the hackles to the sheets, or substitutes for sheets, of vertical or other hackling machines, by which the patentee is enabled to obtain control of the angle which the hackle pins make to the material under operation when they first penetrate it, while they are passing through it, and while they are returning to repeat their action. The invention, therefore, allows of the hackle pins being put in the best position for acting on the flax, and also of their being made to leave the flax at such an angle that the two is left behind them. *Patent completed.*

1153. E. H. C. MONCKTON. *Improved apparatus to be used in warfare, parts of which are applicable to other useful purposes.* Dated April 21, 1862.

The use of electricity and of the above processes as applied to the preparation of iron, steel, and other improved metals to be used in the construction of cannon rifles, armour plates, and other objects used in naval or military warfare, or otherwise as described. *Patent completed.*

1154. J. PICKARD and T. MORRIS. *Improvements in furnaces for the prevention or consumption of smoke.* Dated April 21, 1862.

This consists of a means of effecting or causing the consumption of coal in furnaces, by admitting common air to the front part of the bridge of the furnace in quantities proportioned to the amount and quality of fuel consumed. The air is supplied through the ash-pit, or otherwise to the bridge of the furnace by tubes, doors, or other passages, and passing out of the front part of the said bridge by an opening or openings therein, mingles with the gases and smoke or other products of combustion before their passing over the bridge, causing the perfect ignition or consumption of the same, and effectually prevents the escape of any unconsumed combustible matter through the flues or chimney. *Patent abandoned.*

1155. S. P. MATTHEWS. *Improvements in vices.* Dated April 21, 1862.

This invention consists, firstly, in dispensing with the box and pin, and in lieu thereof applying a pair of portable side plates, in which is fixed a screw lever, the said plates bearing upon side rollers attached to the moveable jaw or

front frame; the aforesaid plates are pierced with pin-holes for regulating the width of grip. Secondly, in attaching to the front jaw or moveable frame three pairs of small pulley wheels, over which a small weight is slung by means of string, catgut, or other material, the weight being a substitute for the spring, but acting on the moveable jaw, or front frame, insures an undeviating power, no matter to what extent the vice is opened. *Patent completed.*

1156. S. F. GRIFFIN. *Improvements in the construction of vessels of war and batteries on land.* Dated April 21, 1862.

In carrying out this invention, the inventor constructs a strong cylindrical-shaped framework, containing in a suitable position a strong gun platform. The upper part of this framework will be dome-shaped, and protected by strong armour-plates of iron or other metal; the lower part may be carried deep into the vessel, and divided, as convenience may direct, into compartments as depots for shot and munitions of war. This framework is suspended by trunnions on a strong circular ring, and such ring or horizontal circle is again suspended by trunnions (similar in principle to the suspension of a ship's binnacle) on a second ring resting on the framework of the vessel, with intervening rollers admitting of the easy rotation of the framework with its gun platform and rings by any suitable gearing. Of course, more than one framework can be fixed in each vessel, and more than one gun on each framework. By these arrangements the inventor expects to obtain the means of keeping the gun platform parallel with the water, independently of the ship's motion, and neutralise to a considerable extent the effect of the gun's recoil, and the impact of shot on the exposed part of the framework. When a vessel is not in action (or from its being so desired), the framework might be prevented from oscillating with suitable fastenings. With some evident modifications, the principle of the improvements hereinbefore set forth may be applied to a land battery. And instead of the binnacle principle of suspension that of the cup and ball may be used for maintaining the equilibrium of the gun platform. The entire outer casing of the gun platform may be lifted up and lowered by steam power or screw power, or other means, so that a gun or guns may be loaded from below, or while below deck line, and the platform elevated and gun pointed, and discharged above the line, or on deck. *Patent abandoned.*

PROVISIONAL PROTECTIONS.

Dated July 11, 1862.

1998. W. Ashton, Manchester, Lancaster, machinist. Certain improvements in machinery employed in the manufacture of braids and similar articles, parts of which improvements are also applicable to machinery used in spinning fibrous substances.

Dated August 27, 1862.

2373. J. A. Coffey, Providence-row, Finsbury-square, and T. Redwood, Montague-street, Russell-square, Middlesex. Improvements in the manufacture of salts of ammonia and other products from the ammoniacal liquors of gas works and animal charcoal works, and in the still or apparatus to be used in such manufacture.

Dated September 25, 1862.

2611. R. Alexander, Islington, Liverpool. Improvements in mariners' compasses.

Dated October 13, 1862.

2760. E. B. Wilson, Parliament-street, Westminster, engineer. Improvements in apparatus employed in the manufacture of iron and steel.

Dated October 15, 1862.

2776. E. Molyneux, jun., Leavien Enniskery, co. Wicklow, Ireland. An improved carriage, with a travelling railway attached.

2778. J. H. Jenkinson, Manchester, cotton spinner. Certain improvements in drink ng fountains.

Dated October 16, 1862.

2795. F. Delmas, Cloak-lane, London, gentleman. A rain absorber.

2802. E. Nelson, Johnson's-place, Ranelagh-road, Thames-bank, chemist. Improvements in the manufacture of apparatus for heating and superheating steam and air without decomposition.

Dated October 20, 1862.

2819. G. Haseltine, Fleet-street, London. Improvements in forging cannon and other heavy articles. (A communication.

2821. J. Clark, Buchanan-street, Glasgow. Improvements in the means of applying railway brakes.

2822. N. R. Hall, Rosherville, Northfleet, Kent, and M. I. Parnell, Strand, Middlesex. Improvements in the construction of thermometers.

2823. W. A. Turner, Lawrence Pountney-lane, London, and T. T. Coughin, King's-place, Stones' End, Borough, Improvements in apparatus for measuring cloths and oth r fabrics, parts of which are also applicable to indicating distances travelled by vehicles.

2825. H. L. Emery, 72, Sloane-street, engineer and manufacturer. Improvements in propelling machinery actuated by the application of animal power.

Dated October 21, 1862.

2828. W. Tristram, Bolton, manufacturer. An improved method of, and apparatus for, preparing and dressing yarns or threads to be employed as warps.

2829. W. H. Tucker, 181, Fleet-street. Improvements in self-closing apparatus for doors.

2831. S. Whitham, iron manufacturer, and T. Wright, manager, Calder Vale Iron Works, Wakefield. Improvements in the manufacture of iron and steel, and in the apparatus employed for that purpose.

2833. C. Clark, 361, City-road. Improvements in cigar tubes, and in cigar and pipe mouth-pieces.

2835. R. A. Brooman, 166, Fleet-street, patent agent. Improvements in waterproofing and in recovering products employed therein. (A communication).

2837. J. Duke and J. Clever, Puriton, Somerset. Improvements in the manufacture of cement.

2839. F. Tolhausen, 17, Faubourg Montmartre, Paris, civil engineer. An improved machine for raising, lowering, removing, and carrying buildings, monuments, and ships or vessels. (A communication.)

Dated October 22, 1862.

2841. G. Clark, 30, Craven-street, Strand, gentleman. Improvements in the construction, protection, and armament of ships, vessels, and floating batteries, some of which improvements are applicable to land batteries and forts.

2842. J. Spence, Her Majesty's Dockyard, Portsmouth, engineer. Improvements in nonconducting compositions for preventing the radiation or transmission of heat or cold, and in coating metallic and other surfaces therewith.

2844. E. Fielding, Willow Bank, near Todmorden, mechanic. Improvements in the manufacture of healds, and in the machinery employed therein.

2845. H. Wilde, Manchester, engineer. Improvements in electro-magnetic telegraphs.

2846. H. H. Kromschroeder and J. F. G. Kromschroeder, Princess-terrace, Regent's-park. Improvements in the manufacture of gas meters, and in the manufacture of sheet metal suitable for gas meters.

2847. E. W. Hughes, 28, Great George-street, Westminster, civil engineer. Improvements in turn tables and turn bridges.

2848. T. Fearn, Birmingham, electro-metallurgist. Improvements in the manufacture of rods, poles, tubes, and other forms employed in the construction of various articles of furniture, and for other similar purposes.

2849. T. Greenwood, Leeds, machine maker. Improvements in machinery for preparing to be spun, flax, hemp, tow, silk waste, China grass, and other fibrous substances.

2850. V. Orlowski, Spring-gardens, Worcester. Improvements in motive power carriages.

Dated October 23, 1862.

2852. W. S. Gamble, Frederick-street, Caledonian-road, Islington. An improved salinometer.

2854. J. Turnbull, Barnard Castle, Durham, brass and iron founder. Improvements in mills for grinding grain.

2856. E. Bath, Port Tennant Copper Works, Swansea. Improvements in treating alkali waste to obtain sulphur therefrom.

2858. H. Rée, Hamburg. Improvements in apparatus for exercising the human body.

2860. E. H. Carbutt and G. A. Clough, Bradford, engineers. Improvements in power hammers.

2862. R. A. Brooman, 166, Fleet-street, patent agent. Improvements in tanning. (A communication.)

Dated October 24, 1862.

2864. C. C. Burmeister, and W. Wain, engineers, Copenhagen. Improvements in the construction of "cupolas," and in apparatus connected therewith, for naval or other war purposes.

2866. J. Gimson, engineer and machinist, and R. Flude, loom maker, Leicester. Improvements in looms for weaving narrow fabrics.

Dated October 25, 1862.

2876. J. A. Nicholson, Gracechurch-street, gentleman. Improvements in lead, crayon, and other pencils.

2878. A. Clark, Brighton. Improvements in the construction of bows and pendants of watches.

2882. J. P. Bourquin, Newman-street, Oxford-street, album manufacturer. An improved manufacture of mount for photographic and other albums, miniatures, and other pictures.

Dated October 27, 1862.

2884. J. H. Johnson, 47, Lincoln's-inn-fields, gentleman. Improvements in rotatory engines. (A communication.)

2890. F. L. H. W. Bünger, 5, Gloucester-place, Brixton-road, civil engineer. Improvements in self-acting apparatus for discharging the water resulting from the condensation of steam. (A communication).

2892. P. E. Placet, Cite Gaillard, No. 5, Paris, civil engineer. An improved process of engraving.

2894. A. Peek, Manchester, manufacturing chemist. Improvements in apparatus for evaporating saccharine and saline solutions.

2996. J. Howie, Hurlford, Ayr, coal master. Improvements in machinery or apparatus for regulating the supply of solid or liquid bodies to mills. or other apparatus used in mixing or preparing plastic matters.

Dated October 28, 1862.

2898. E. Hooper, Southampton. Improvements in roofing tiles.

2900. E. and A. Tatham, Ilkeston, Derby, lace manufacturers. An improvement in warp machines for the manufacture of looped fabrics.

2906. T. Sutton, Bachelor of Arts, St. Brelade's Bay, Jersey. Improvements in preparing albumenized paper for photographic purposes.

Dated October 29, 1862.

2916. W. E. Evans, 8, Newton-terrace, Bayswater. Improvements in apparatus for playing organs, harmoniums, pianos, and other similar keyed instruments, and also improvements in reed musical instruments.

2918. W. E. Gedge, 11, Wellington-street, Strand. Improvements in looms for weaving. (A communication.)

2920. J. Head, Steam Plough Wharf, New Swindon, Wilts, engineer. Improvements in machinery employed when cultivating land by steam power.

2922. F. L. Stott, Rocndale, machine maker. Improvements applicable to mechanism or apparatus for warping yarns or threads.

PATENT APPLIED FOR WITH COMPLETE SPECIFICATION.

Dated October 30, 1862.

2935. G. Haseltine, 100, Fleet-street. Improvements in horse shoe machines. (A communication.)

NOTICES OF INTENTION TO PROCEED WITH PATENTS.

1897. G. H. Hulskamp. Pianofortes.

1905. J. Wall, and T. Dodd. Taps for controlling the flow or passage of fluids.

1915. E. F. Prentiss. Construction of omnibusses and other four-wheeled vehicles.

1918. C. Lungley. Constructing, building, and working floating docks and other floating bodies.

1920. J. and J. Greenhalgh. Diminishing valve.

1923. W. E. Newton. Washing wool. (A communication.)

1929. T. L. Atkinson. Stewpans.

1930. G. H. Hulskamp. Violins.

1931. J. Murray. Portmanteaus.

1932. J. Steel. Water closets.

1933. J. Crisp, and J. W. Elliott. Apparatus for burning American rock oil.

1935. G. Bedson. Rolling wire and other rods or bars of metal.

1936. J. M. Hetherington, and T. Jackson. Preparing, spinning, and doubling fibrous materials.

1939. W. A. Gilbee. Manufacture of blue colouring matter. (A communication.)

1943. J. Miles. Cutting out soles and other parts used in the manufacture of boots and shoes.

1945. W. J. Cunningham. Sewing machines.

1946. A. Drevelle. Apparatus for laying cards or sheets of metal into woven or textile fabrics.

1948. J. Howard and J. Bullough. Warping and beaming machines.

1953. A. Warner. Preparing materials for, and in purifying coal gas.

1960. W. Spence. Telegraphic apparatus. (A communication.)

The full titles of the patents in the above list can be ascertained by referring back to their numbers in the list of provisional protections previously published.

Opposition can be entered to the granting of a patent to any of the parties in the above list who have given notice of their intention to proceed, within twenty-one days from the date of the *Gazette* in which the notice appears, by leaving at the Commissioners' office particulars in writing of the objection to the application.

LIST OF SEALED PATENTS.

THE

MECHANICS' MAGAZINE.

LONDON, FRIDAY, NOVEMBER 21, 1862.

NAVAL GUN AND ARMOUR EXPERIMENTS AT SHOEBURYNESS.

The experiments which took place last week at Shoeburyness, in their character and results, are the most important and interesting which have occurred. They have a double bearing on our national defences, relating as they do to naval guns and naval armour. The significance attached to them in the highest quarters, and especially by our rulers, may be inferred from the *quasi* official reports in the *Times*, and the apparent spirit of candour, in which a leading article in that journal affects to do justice to Mr. Whitworth. It will be remembered by those, who have read the former reports of artillery and target experiments, which from time to time appeared in the columns of our great daily contemporary, that those occurrences were made the occasion of fulsome and extravagant panegyrics on the Armstrong ordnance or the "Warrior's" armour. The gun and the frigate were, in stilted language, declared to be unrivalled, and the country was again and again congratulated on the fact, that the possession of the one and the other gave England the pre-eminence over all other nations. We have often had occasion to point out the inaccuracy of those statements, and have warned our readers against placing full credence in them. We were well aware the real object of these laudatory reports and leaders was to support the two favoured Government enterprises, the Armstrong and "Warrior" pets, and "*coute qui coute*," to maintain their fading reputation. It was uphill work for the poor journalist. In spite of his efforts, he could not conceal facts published in the Mechanics' Magazine, which proved that the 110-pounder rifled Armstrong was less damaging than the old 68-pounder smooth bore, and that the "Warrior" armour was an imperfect defence against heavy guns. We joined in, if we did not lead the cry of indignation, spread far and wide, at the partiality, which was a barrier to the trial of better guns and better armour. Time and perseverance have at last wrought a beneficial change, and the results of recent experiments have lowered the boastful attitude of the official organs to one of humility and common sense.

We make these remarks as an introduction to our account of the gun and armour trials referred to, in order that the public may understand the real nature of the situation, with reference to two branches of expenditure, which have already cost the country more than six millions, to very little good purpose. It may be said, that the Government's difficulty is the nation's opportunity, which gives a chance to the economical party to strike home, and put a stop to wasteful expenditure on a monstrous scale.

In some of the leading features, and many of the details, our reporter's description of the trials at Shoeburyness, on Thursday and Friday last, differs materially from the reports of the *Times*. We invite attention to those differences, because they indicate, on the part of the Armstrong and Ellswick party, a determination not to give up the game as lost, but, on the contrary, by new combinations, to maintain their grasp on the public purse. The *Times* tells us, "Sir William Armstrong is not idle, and appears satisfied with the results" of some experiments which came off on Friday, when Mr. Whitworth and his friends were absent.

The authorities having, from circumstances, found it impossible to evade a fair trial of the Whitworth ordnance, the essential business on the first day (Thursday) was to measure the force of the Whitworth guns and projectiles against the Armstrong. The *Times'* reporter, following his cue, represents those trials as a duel between Guns and Armour. They no doubt have served to prove conclusively the radical weakness and total inefficiency of the "Warrior" system, which we have so often explained and insisted upon; but the real question at issue was the performance of the Whitworth, as compared with the Armstrong Artillery. The intense interest displayed by Sir William in the effect of every shot, proves how closely he felt the trials of that day concerned him; and he evidently felt, like everybody on the ground, that this was a contest for supremacy between him and his rival—that it was, in fact, the very crisis of his fate. The target fired at was only the medium for the experiments, although the results produced upon it have an astounding influence on the Naval Armour question.

The target set up for the occasion has been reported as similar to that of the "Warrior" section, but it differed in some particulars, and upon the whole was stronger, so that the chances were slightly against Mr. Whitworth. The backing, 18 in. of teak, was the same as that of the "Warrior," but the frames were closer together by 3 or 4 in., which gives greater support to the skin and backing; two of the three plates, which covered the target, each 3 ft. 4 in. wide, and about 15 ft. long, were 5 in. thick, being an advantage over the "Warrior" of ½ an inch.; and the ends of the target were supported by 7 ft. of balks of timber, against which the frames and skin abutted, and were secured in the most solid manner, the whole being shored up behind by stout wooden struts and stauncheons. The side supports, which added greatly to the power of resistance of the structure as a whole, and were not used in any previous target, formed the side walls of a chamber at the back, which was closed in behind and represented a portion of a deck with its ceiling and floor, access to it being provided for by an iron-plated door. The target, therefore, was stronger than the "Warrior" section, against which the Armstrong 100-pounders were fired without penetrating the plates, and the test was so much more difficult for the Whitworth experiments. The two 5 in. plates were part of the Samuda dismantled target, which so signally failed some months ago. The 4½ in. plate was one of the old "Warrior's." The former were rolled and made by J. Brown and Co., of Sheffield; the latter was hammered and made at the Thames Works. The iron of all three was of excellent quality. The 5 in. plates were fastened with through bolts, 9 in. apart, along the edges, longitudinally—not, as the *Times'* reporter surmised, to avoid perforations through the middle of the plates, but simply because they were so prepared on Mr. Samuda's plan, which, before his target was tried, we pointed out as a source of weakness, (on trial, it proved to be so,) in consequence of the perforations being within 2 in. of the edges of the plates, and, therefore, exposing them to easy fracture.

Two Whitworth guns were tried—a 120-pounder at 800 yards, a 70-pounder at 600 yards range, both rifled muzzle loaders. The rifling of the guns, and consequently the form of the projectiles, shot or shell, is a spiral hexagon, although for the matter of any difference in penetrating effect, the shells may be regarded as shot, for they do the work of penetration equally well, but they differ in length, being elongated to form the chamber for the bursting charge. The diameter of the larger projectile is 6 in. at the faces, and 7 in. at the angles, giving a mean of 6½ in., and that of the smaller 5¼ and 6¼ in., giving a mean of about 5½ in. The length of the 120-pounder shell, which at the trial of this projectile, in September last, was 17 in., with a bursting charge of 2½ lbs., was, on this occasion, 21 in.; Mr. Whitworth having been taught by experience the necessity of increasing the bursting charge, which now is 5 lbs. We do not give the particulars of the smaller shell, its effect not being conclusive, in consequence of the insufficiency of the bursting charge. The results obtained by the Whitworth projectile have to be considered in a twofold aspect—damage to the armour by penetration, destruction to the ship and crew by explosion. But here a new feature, which, if we mistake not, is an important discovery in gunnery, presents itself. The same projectile can be used as a solid shot or shell indiscriminately, and with equal effect in either form. The advantages of this double character, into the details of which it is unnecessary now to enter, must be apparent, and give a new interest to Mr. Whitworth's valuable invention. There is another point to which we draw especial attention, and that is the comparative penetrating force of the 6½ and 5½ in. projectile, because we shall have to adduce, from the results obtained, conclusions which may prove that the art of constructing invulnerable armour is much less speculative and uncertain than it hitherto has been. It remains for us to mention that the material of the Whitworth shot and shell, of which any serious damaging effect has to be recorded, is not cast-iron, but homogeneous iron or steel. It is, in fact, to this adaptation of material Mr. Whitworth is mainly indebted for his great success; for it is now established beyond a doubt that cast-iron shot will not do the work due, to its projectile force, upon the armour, as it expends a great part of that force in destroying itself. The steel shot is the steel punch. Who would think of using a cast-iron punch? The Whitworth shot are called flat-headed, and the first he made were literally so; but he has seen reason to modify the striking face by making about half its diameter in the centre convex, with a flat ring, slightly tapered, outside. This convexity, it is thought—and we believe with reason—facilitates generation.

Sir W. Armstrong has taken up the same idea in giving a round head to his new projectile, which, it is announced, will beat the flat heads, and we incline to think that will prove to be the case. His first rifled cylinders, employed for target experiments, had conical heads, terminating in a slight convexity about an inch in diameter. This form was designed to cleave the air with a minimum loss of velocity, and for light field guns and shell, intended to burst in the air at long ranges, it was efficient; but it woefully failed when applied to a battering projectile hurled against iron plates. The pointed nose broke off, and the main part of the cylinder fell innocuous at the foot of the target. In this matter, as in many others, the talented Director of Artillery has profited at the public expense.

The reader will now be able to follow our notice of the experiments with better means

of judging the results, and the causes to which these are due.

Before the experiments commenced, 5 pilot shots—3 from the 120-pounder and 2 from the 70-pounder—were fired at a wood target to obtain the range. This necessarily occupied some time, but it by no means implies a doubt of the accuracy of the guns, as the *Times* unfairly insinuates. It was the usual and proper precaution to insure precision in the experiments, and one always taken preparatory to trials of Armstrong guns, on which occasions it passed unnoticed, or at least called forth no sarcastic remark from the pen, which, through good or evil report, and in spite of disastrous failures, unflinchingly fought the battle of the official favourite.

The first trials were made with the 120-pounder, from which 5 shell and shot were discharged at the target. No. 1 (shell), weighing 150 lb., including its bursting charge of 5 lb., and fired with 25 lb. of powder, hit the centre (5 in.) plate with a velocity of 1,210 ft. per second, a few inches from the bottom, about an equal distance from both ends. It made a breach right through the plate into the teak backing, and exploded when partly imbedded in the wood, before it had passed through the plate. There can be no doubt on that point, because the screw-plug was forced 50 yards in front of the target in a diagonal direction, so much to the right, that the tail of the shell must have been outside the breach when the plug was blown off. A few broken pieces were picked up outside, and several larger ones were jammed inside the backing, which was torn into shreds resembling cocoa-nut fibre. The ¾ in. plate, representing the ship's skin, was burst open full 10 in. in every direction, and a frame was smashed in two places. Some pieces of shell and plate penetrated inside the deck chamber, but apparently not with much force, judging from the slight marks on the timber and iron lining. Three bolt-heads were started, protruding so far as to leave no doubt they were broken; three more were slightly started, and the points of two bolts, with their nuts, were sheeted off inside. The armour-plate was driven into the wood backing half an inch at the part struck, and buckled outwards at the ends more than one inch. To this effect, which is the invariable result of the yielding nature of wood, the rupture of the bolts is to be attributed. Similar effects, varying only in degree, were produced by the other shell and shot from the 120-pounder; in one case, seven bolts out of fifteen, which held the plate, were broken.

No. 2, another 150-pounder shell, with the same gun and bursting charges (25 lb. and 5 lb.), and 1,220 ft. velocity of impact, penetrated the top plate, which is 4½ in. thick, near to the bottom, and the explosion again took place in the wood backing, but the destructive effects were greater than those of No. 1, owing to the diminished resistance of half an inch less thickness of plate. The hole was larger and cleaner cut—the penetration into the backing, before explosion, deeper—the skin and one of the frames were more extensively smashed inwards, and splinters from the shell and plate were scattered with violence in all directions inside the chamber, many of them being driven into the wood lining. The teak backing was driven out at the top, and for some time emitted volumes of smoke, showing it was ignited. The plate was much dished, and seven bolts were broken.

No. 3, a cast-iron solid shot, weight 130, charge 27 lbs., which brought the velocity of impact up to 1,260 ft. per second, hit the centre plate near the top, close to a bolt-head, cracked the plate across the bolt-hole, but did not pierce through the plate, and broke up. There was a deep indent, the plate driven 3½ in. in at the top edge, and brought out ½ in. at one end; but there was no damage to the skin, and no penetration into the backing. These negative results, with an increased velocity, prove how much of the effect of the projectile punch depends upon the material of which it is made. Great part of the force of this shot was lost in destroying itself.

No. 4, a 130 lb. shell, with a gun charge of 27 lb., and a bursting charge of 3 lb. 12 oz., attained an impact velocity of 1,280, the highest in these experiments. The comparison of this shell with Nos. 1 and 2, which were fired with only 25 lb. of powder, is instructive. The problem to be solved was the effect of an increase of projectile force, by reducing the weight and increasing the velocity, in proportions, which give a better result in multiplying the square of the velocity by the weight, and the results justified the expectations of Mr. Whitworth. The effect of this shell is incorrectly reported in the *Times*, which says that "*it did no less than the former shells had done*, going through all and bursting inside, but it also did no more." Here is a glaring inconsistency, for the two first shells did not penetrate through the target, and this did; and the destructive effects of the latter inside the chamber were greater, although the bursting charge was less. This arises from the fact that the increased velocity sent the shell, if not right through all, much deeper into the backing, before it exploded. The missile struck the centre of a 5 in. plate, burst through it, making a hole clean cut outside to the thickness of an inch, but inside the remaining thickness of the plate was rent asunder, making a cavernous opening 12 to 15 in. in diameter; the fragments of iron were forced in by the shell, of which the base was found inside the chamber, with smaller splinters of shell, plate, skin, bolts, nuts, and rivets, and debris of wood, which, collected in a sack, was a good weight for a man to carry. No pieces of shell were found outside; the plate was cracked across a bolt hole; a gaping aperture, 12 by 10 in., was made in the skin, and the damage altogether exceeded that of any preceding shell or shot. The loss of life and limb to a new between decks would have been terrible.

No. 5, a 130-pounder solid shot of homogeneous iron, with a 25 lb. charge, and an impact velocity of 1,240, hit the middle plate a little below the centre. The objeet of this experiment was to determine the penetrating power of the Whitworth hexagonal, unaided by a bursting force in its interior. The success was complete; the destroying bolt sped its way unchecked through 5 in. plate, 18 in. of teak, ¾-iron skin, and an iron frame, crushing its path through all into what may be termed the chamber of death. The head and fore part of this terrible messenger, measuring 10 in. in length, was found in the chamber, having struck against what may be regarded as the other side of the ship, and left an indentation on the iron plate lining. The tail part, measuring 5 or 6 in., was torn away in the fierce struggle to force a passage. The head was set up at the moment of impact, its diameter being increased from 6½ to 8 in. The hole in the plate at its orifice was enlarged to 8½ in. in diameter, and torn open inwards, 12 to 15 in. The breach through the skin plate was a jagged gaping wound. Bolts were started and sheered off, but not in such great number, as before not many remaining to be destroyed.

This shot, as the climax of the effects of the 120-pounder, satisfied Mr. Whitworth, and brought the experiments with that gun to a close.

A series of trials, similar in arrangement to those first described, followed with the 70-pounder gun, but the results were far from being equally satisfactory to Mr. Whitworth. This gun did not do what the 120-pounder did. Not one shell or shot penetrated through the target, or even fractured the skin plate. We need not give the details of the four experiments which completed this series, but will briefly state the nature of each, continuing the numbers from the former series to prevent confusion.

No. 6, a 70-pounder live shell, gun charge 13 lb., bursting charge 2½ lb., impact velocity 1,160.

No. 7, 80-pounder live shell, gun charge 13 lb., bursting charge 3 lb. 12 oz., impact velocity 1,158.

No. 8, 70-pounder live shell, bursting charge 2½ lb., with increased gun charge, the velocity being augmented to 1,200.

No. 9, 70-pounder blind shell, without bursting charge, and, we believe, with 15 lb. gun charge.

Not one of these missiles produced the desired effect. No. 6 and 8, discharged against the 4½ in. plate, were the most effective, but the utmost extent of the work was to penetrate into the plate. They could not pass through it. The assault against the 5 in. plate was a greater failure. No. 7 having, by a desperate effort, with an increased charge, marked the circular crack of a core which was slightly driven in, but not through the plate, recoiled and fell to the ground a spent shot, in front of the target. No. 9 was the great effort. It was fired under the same conditions as the 130-pounder, No. 5, intended, with an increased charge, to penetrate without explosion, but its force was not equal to the task. The projectile doubled up and destroyed itself. Something was said about the quality of the iron, but we believe the truth is, that the 70-pounder has too much work to do against 5 in., and even 4½ in. plates. Mr. Whitworth, evidently chagrined at these disappointments, abandoned the further trials comprised in his programme, and these most interesting experiments were concluded.

It now remains to institute a comparison between the two series of experiments, from which important conclusions are to be drawn, but space compels us to be brief. The grand feature of distinction between them is, that the 120-pounder has penetrated a "Warrior's" armour and hull, and half an inch of iron to boot, with shot and shell, with the utmost facility. The 70-pounder completely and signally failed to drive either shell or shot through the armour plates, much less to damage the hull. The destroying effect of the latter on the fastenings is considerable; but this is to be attributed more to the through bolts and wood backing, which are proved sources of weakness, than to the force of the shot. To a certain extent, that is, as regards the wood backing, the same may be said with reference to the 130 and 150-pounders, whose penetrative powers met with little resistance after they had passed through the armour plates. It is in the direction of backing that we must look for the means of rendering ships' armour impenetrable.

This great duel is a trial of supremacy between two systems of ordnance, on which much remains to be said. Sir William is beaten in this contest, but he is not vanquished. In this eager conflict for victory in the attack, let us not lose sight of the defence, which may, notwithstanding the

contrary opinion of artillerists, prove to have the best of it. The close analogy between the penetration of iron plates by projectiles, and the ordinary punching process, to which we first drew attention, is attracting the notice of men of science and engineers. It is a significant fact that the Whitworth 6½in. flat heads pierced through and through 4½ and 5in. plates, those being less in thickness than the diameter of the projectile, but the 5½ in. projectile could not penetrate the 5 in. plate.

We leave the question there, for the present, and we must postpone our notice of the second day's experiment, to our next number.

THE FOREIGN LOCOMOTIVES IN THE INTERNATIONAL EXHIBITION.

(*Continued from page* 308.)

THE Paris and Orleans Railway Company sent a six-wheeled outside-cylinder, express passenger engine and tender, made at their works at Ivry. The eccentrics and links are outside the crank pin; the steam chests being also outside the smoke-box. Cylinders, 15¾ in. diameter, and 25½ in. stroke. The driving wheels are 6 ft. 7¾ in. in diameter; the leading and trailing wheels, 4 ft.; the total wheel base, 14 ft. 1 in. The leading axle-boxes have a lateral play of three-fourths of an inch. The fire-box heating surface is 96 square feet; the tube surface is 1,046 square feet. The tender contains 1,233 gallons of water, and about two tons of coal. This engine burns coal according to the plan of M. Tenbrinck. The general principle of this plan is the one running through most of the successful English and foreign coal-burning arrangements, namely, that of deflecting air into the firebox *above* the incandescent fuel in just sufficient quantity to mix with the products of combustion without cooling them down. The carburetted hydrogen gases issuing out of coal are always consumed without smoke if sufficient oxygen be given them without at the same time lowering their temperature to any great extent. Probably each of the different coal-burning plans has some special advantage, adapting it to the particular kind of coal it is intended to consume. Other things being equal, the simplest plan is of course the best.

M. Tenbrinck places the grate at a considerable slope downwards, causing the fuel to descend gradually as the combustion goes on. The grate is formed of two sets of firebars, the lower set being nearly horizontal. There is a common firedoor, but it is only used for cleaning the tubes. Below this ordinary firedoor are two openings extending the whole breadth of the fire-box. The top inlet, closed by a valve, is for the admission of the air, and the lower one is covered by a case into which the fuel is introduced by lifting up a door on hinges.

A water-table or flue is placed across the firebox above the sloping grate, and parallel to this latter. The flue deflects the air on to the fire below it, as the air issues from the upper opening. This diaphragm also replaces, to some extent, the heating surface lost by the great slope of the firebars. This system is said to be much liked in France, although, we should say, that it contains several objections.

We alluded, in our preceding number, to Mr. Belpaire's coal-burning arrangement, as being employed on the large French goods' engine then noticed. In this other plan, the grate is brought up on a level with the footplate, so that, if required, the trailing axle may be placed underneath the firebox. The grate is very long, and is made up out of five lengths of firebars. The firedoor is very large, and it is formed of two fire-brick plates, made with holes, which are regulated by slides, for the passage of the air on to the top of the burning fuel. The firebars are peculiar, being very narrow and close together, which must render them very difficult to keep clear of clinkers. We do not think that this plan of coal-burning would sufficiently consume the smoke of our English coals. Slack coal is said to be principally used in these engines. As is also usual in England, there is a steam-blower in the smoke-boxes of these coal-burning engines. It is mostly used when the engine is standing at the stations, as a substitute for the blast-pipe; and, it has a similar action, increasing the draught, and throwing down the smoky particles by means of the steam getting condensed within them.

Messrs. J. F. Cail and Co., and Messrs. Parent, Schaken, Caillet, and Co., jointly sent a 6-wheeled coupled, inside cylinder goods-engine, with 18-in. cylinders, 24-in. stroke, and 5-ft. wheels. The coupling rods look very light, being of steel. This engine has Mr. Caillet's peculiar arrangement for passing sharp curves. According to this plan, the leading and trailing wheels are capable of shifting transversely to the engine. Horizontal springs are arranged to bring back the leading and trailing axles to the central position.

The State Railway Company of Austria sent two locomotives, built in their large workshops in Vienna. These workshops—the most extensive in that country—have been for nearly 20 years under the management of Mr. John Haswell, one of our countrymen. One of these engines is an express locomotive, of a very original design, first proposed and carried out by Mr. Haswell. It is one of 12 engines lately built by this gentleman, exactly similar in every respect to the one exhibited, with the exception that the latter has, on each side, *two* double cylinders, each pair being cast together. It is an engine with outside framing, and the 3 axles are to the front of the fire-box. The wheel-base is only 11 ft. 5 in. The driving wheels are 6 ft. 9 in. in diameter, and are placed in front of the fire-box. The load on the driving wheels is about 12¾ tons. The weight of the engine when full is 32 tons. The area of the grate is 15 square feet. The total heating surface is 1,344 square feet, 1-16th of which belongs to the fire-box. The feed apparatus consists of 2 of Giffard's injectors. The 2 double cylinders are 11 in. inside diameter, and 25 in. stroke. Their axles intersect each other in the centre of the driving axle. Each axle is at an angle of 2½ degrees, with a horizontal line from the centre of the driving wheel. The connecting-rod of the top cylinder works a crank, keyed on to the driving axle, which is prolonged outside the frame. From the crank pin a strong steel bar is carried back on the same line as the above-mentioned crank, exactly opposite, and to the same distance from the centre of the axle. Another pin on this bar is worked from the connecting-rod of the lower cylinder. The pistons of each pair of engines are thus made to move in exactly opposite directions, and the reciprocating parts are thereby completely balanced at all speeds, a result impossible to be obtained by the usual arrangement of revolving balance weights. Rotating balance-weights, of course, cause a changeable load on the driving wheels, their influence varying as the square of the velocity.

Each pair of cylinders is worked by a single valve and link in a rather ingenious manner. There must, however, be a great waste of steam in the passages, as the valve face is evidently so far off. This engine has been completely successful in the main intentions of its peculiar design. At a speed of nearly 70 miles an hour, and with a load of 50 tons, it has run with perfect steadines. Last February it was tried in the shop, being hung up by the chain of a crane, so that the driving wheels were 2½ in. above the line of rails, and the leading wheels resting on these latter. At 400 revolutions per minute, the horizontal oscillation was only about 1-12th of an inch, the vertical oscillation being 1-5th of an inch.

This engine is called "the Duplex." We have heard some severe criticisms upon it, coupled with the proposal to re-christen it "the Complex." We cannot help confessing to an admiration of the way in which the complete balancing of the reciprocating parts has been carried out; it is to some extent a revival, in much improved shape, of an invention of that veteran schemer, Mr. L. R. Bodmer, of Switzerland, and formerly of Manchester. According to that gentleman's plan, the cylinder of an engine was to have two pistons, and two piston rods working one within another, with a connecting rod to each; the pistons alternately advanced to, and receded from each other in the cylinder. We believe that there are one or two large engines upon this plan still extant in the Lancashire districts. They require an occasional "doctoring up." One of the weak points of this latter arrangement consists, of course, in the tubular outside piston rod, which continually causes trouble, particularly from the necessarily weak attachment to its piston.

The other Austrian locomotive was also made at the works managed by Mr. Haswell; it has been proved capable of drawing about 200 tons load up an incline of 1 in 40, with curves of 300 feet radius, at a speed of about 10 miles an hour. It is a goods' tank engine, with ten wheels coupled; the cylinders are outside, 18 in. in diameter, and 25 in. stroke; the wheels are 3 ft. 3½ in. in diameter, being all coupled together in a peculiar manner. The boiler rests on two frames, coupled together by a pin, allowing them to swivel on passing round curves. The fore part, carrying the working gear and the front end of the boiler, has six wheels, with a wheel base of 7 ft. 4 in. The hind carriage, carrying the tender and the fire-box, has the four other wheels, also with a wheel base of 7 ft. 4 in. The total wheel base is 19 ft. 5 in. The heating surface of the fire-box is 78½ ft., the inside tube surface 1,244½ ft., giving a total of 1,323 square feet. The boiler is fed by two No. 9 injectors. The wheels are cast-iron discs, with steel tyres, and the balance-weights are cast on the wheels. The engine is fitted with a steam break. The engine, when in working trim, weighs about 46 tons, with a maximum load on a pair of wheels of about 12 tons 2 cwt. The remarkable peculiarity about this engine, as we mentioned before, consists in the arrangement whereby all the 10 wheels of the swivelling frame are coupled together, with the view of obtaining a greater amount of adhesion for ascending the steep inclines. We do not feel capable of making this arrangement fully plain without a sketch.

The engine from Prussia fully keeps up the name of the well-known shops of Borsig, of Berlin. This establishment has turned out more engines than any other works on the Continent. It is a 6-wheeled, 4 wheels coupled outside cylinder goods' engine. The cylinders are 17 in. in diameter, and 22 in. stroke. The driving and trailing wheels are 4 ft. 6 in.,

the leading wheels 3 ft. 4 in. in diameter. There are two slide valves to each cylinder, with a separate expansion link to each valve, so that there are in all four links. The engine, when full, weighs 32 tons, of which eight tons are on the leading wheels. The heating surface of the fire-box is 65 square feet, that inside the tubes 960 square feet. The maximum pressure of the steam is 100 lbs. per square inch. The tender carries 1,150 gallons of water, and two tons of coal. The cast steel rods, &c., look very light to an eye accustomed to wrought-iron proportions.

The Saxon engine, made by Hartmann of Chermutz, is a 6-wheeled, four wheels coupled engine. The outside cylinders are 15 in. in diameter, and 22 in. stroke. The leading wheels are 2 ft. 7½ in. in diameter, the driving and trailing wheels, 4 ft. 6 in. This engine when full weighs 28 tons. The fire-box heating surface is 70 ft.; the tube surface, 790 ft. The two leading wheels are arranged to form a "Bissell" truck. This is to meet the sharp curves (275 ft. radius) of the Saxon mountain railways.

The Belgian engine was sent by "La Société Anonyme des Hauts—Fourneaux, Usines et Charbonnages de Marcinelle et Couillet," Hainault. The fire-box is upon the slack coal-burning plan of M. Belpaire, a Belgian engineer. We have already alluded to this arrangement. It is a 6-wheeled coupled goods' engine. The inside cylinders are 17½ in. diameter, and 23½ in. stroke. The wheels are 4 ft. 9 in. in diameter; the wheel base is 13 ft. 1½ in. The heating surface of the fire-box is 86 square feet: the tube surface 1,141 square feet. The engine, when full, weighs 33 tons 9 cwt. The load on each pair of wheels was 11 tons 9 cwt. A little peculiarity of this engine that we have also noticed in some of the French engines, consists in the fashion of planing out the insides of the coupling rods, so that the cross section has the shape of a double-T. We suppose that this is done for the sake of lightness. The arrangement for reversing is rather neat. An ordinary reversing handle is worked by a screw, so that the link can be set to any position, without being tied to certain fixed positions, as in the links of the common reversing sector. The reversing handle can be disengaged from this screw if it be required to reverse the engine suddenly.

The engine from Naples demonstrates pretty clearly that reform is required in the locomotives, as well as in the political system of that country. It is a 6-wheel coupled goods' engine. The boiler barrel is not merely oval, to the extent of several inches, but also conical, being made larger at the fire-box end, and tapering towards the smoke-box. The coupling rods have merely brass brushes, with no arrangement to take up the wear. The man-hole is actually placed in the smoke-box tube plate. According to its bill of loading, we see the exhibitors put a value upon it of no less than 135,000f. The weight is given at 27 tons. They estimate it as an engine of 40-horse power! The reversing gear is balanced rather neatly by means of a large spring balance.

Several of the engines we have noticed have received medals and "honourable mentions." As these "awards" have evidently been given by some occult process, depending more upon the luck of the exhibitors than the wisdom of the jury, we have not alluded to them. We have an opinion of our own about these awards generally. We believe that the juries of the different classes wrote the names of the different exhibitors on little slips of paper, put them into a hat, shook them up in some instances, and drew forth the names of the "fortunate" receivers of the prize medals.

This review of a collection of locomotive engines, from almost all parts of the Continent, will show that we do not suffer by comparison in this department of mechanical science. In the matter of communication generally, which may briefly be said to be the same thing for a country as the circulation of the blood for an individual, we English have always shown a good example to the rest of the world. In the business of inland communication we first brought road-making into a system, and placed on our macadamised roads the finest horses of the universe. These not being found fleet enough and strong enough for our purposes, we have made iron roads and iron steeds. Having superseded the stage coach, we are now making traction engines to supersede the cart horse. IT.

IRON WALLS AND NAVAL GUNS.

TO THE EDITOR OF THE "MECHANICS' MAGAZINE."

WOOD BACKING.

SIR,—The last experiments at Shoeburyness have added new interest to wood backing. My reply to Mr. Cheverton affords the opportunity of expatiating on this subject to some better purpose than a controversy with a theorizing critic. I cannot let his personal remarks pass unnoticed, but I will be as brief as possible in dealing with them. In a strain hardly consistent with good taste in a scientific discussion, Mr. Cheverton begins with a sneer, and ends with slang. He terms opposition to wood backing a *crotchet*, and finding I am in search of something better, "he wishes I may get it." This is the absolute style of the scientific, as it is of the political republican. You must believe in his doctrine, or come under his lash. "Perdition to the colonies rather than abandon a principle," cried Mirabeau. "Nothing like leather," said the tanner. "Nothing like wood," says Mr. Cheverton. He clearly is a man of wood; let us see on what basis his predilections are founded. I do not wish to be hyper-critical; but, after carefully following his argument, I cannot see that it amounts to anything more than this assertion—"that, if "*enough of it* is employed, wood will keep out "cannon-shot," and he estimates 5 ft. in thickness as sufficient for that purpose in the case of a 68-pounder. I take it that, in accordance with his calculations, to stop the shot of 120 and 150-pounders, which undoubtedly will become service guns, 10 to 15 ft. in thickness of the ligneous material will be requisite. To say nothing of the difficulties of construction with such masses of timber, I should like to know the recipe of the author of this notable idea for preventing destruction by incendiary shells. He may reply, "I never made so absurd a proposition." *Cui bono*, then, to moot it. Why simply to obtain the petty triumph of proving that wood does offer SOME resistance. The meaning of my words, "little or no resistance," is obvious—namely, as backing to armour-plates for any practical or useful purpose. I totally dissent from the proposition that wood is "of great value as a backing for the sake of its resistance," and I regard this idea as so dangerous a fallacy that I oppose it, as I have done for more than twelve months, with all the energy of profound conviction. It is the prejudice of the wood school, as opposed to the men of iron, and has cost the country millions, wantonly wasted on a theory which, unfortunately, in the construction of our iron-cased navy, has been acted upon to an enormous extent without previous experiment. Call it a *crotchet*, if you please, but the total inefficiency of wood as a backing to iron armour—nay, its positively damaging character as a destructive agent—are *truths* so strongly impressed upon my mind, and established by conclusive experiments, that, in spite of the cavilling and railing of professional authority, as Galileo, in the midst of persecution, exclaimed, "The earth goes round," I shall insist upon the utter worthlessness of wood as a backing to armour plates.

"To aid the armour plate in repelling the blow" is "the first duty of backing." Let us see how wood performs that duty. At the moment of impact the first effect on the plate is an indent on the face and a bulge at the back, if the plate is not supported by a backing sufficiently rigid to resist or attenuate the force. This bulge is the beginning of the mischief; if it is not checked, the projectile force being sufficient, the bulge enlarges and bursts open and the projectile penetrates; but if the bulge at once encounters a rigid local resistance, the resisting medium, although it may be shattered, will tend to repel the projectile and cause it to recoil whole or in fragments. The utility of wood backing as an absorbent of the shock to the structure, as a whole, is undeniable; this comes from its yielding nature, but this very nature is the source of an evil of the greatest magnitude. The yielding of the backing causes the plate to be driven inwards bodily over an area of some feet around the point struck, and to buckle outwards at its extremities. The effect of this action, which a hundred experiments prove to be invariable, is disastrous: the fastenings, no matter what their nature may be, are violently rent asunder, and the plate thus separated from its holdings, would, with a rolling motion at sea, tumble off the side of the ship. Far better to have the armour riddled with shot holes, which might be plugged, than forty or fifty feet of surface left totally unprotected. The Duke of Somerset declared in the House of Lords that he had repeatedly, at experiments, seen plates fall bodily off the side of the ship; and I aver, as I have again and again before stated, that wood backing is the cause of this great calamity.

In the trials last week with the Whitworth shells this destructive action on the fastenings was clearly attributable to the wood backing. At whatever point a plate was struck it was more or less *dished*, that is, made slightly concave over an area of which the shot-hole was the centre, and buckled outwards at one or both extremeties. These results, which are entirely due to the yielding and elastic character of teak backing, told fearfully on the bolts, of which, to give an example, *7 out of 15 which held one plate were broken by a single shot*. If there were no other objection to wood as backing, this effect, which is invariable in a greater or less degree, alone condemns it.

Mr. Cheverton kindly informs me that to punch a hole in a plate, the latter is placed on a firm and solid bearing over the die, and he pities my ignorance or what he politely terms "want of practical knowledge in the manipulation of metals," because he supposes I am unacquainted with the common process of punching holes in boiler plates. But I refer to the very case I put with reference to punching as proving his mistake; and I must be so uncourteous as to retort that his illustration is not apposite, and his argument is a *non sequiter*. My proposition was, "If, in the ordinary punching process, a man wished to prevent the punch passing through the plate, would he as an obstruction, place under it

(that is, between the plate and the die) a wooden plank," and I reply, "certainly not," for the punch would go clean through the wood. But if a hard and unyielding substance were interposed the result would be different. Mr. Cheverton arrives at the conclusion, that because a plate being placed on a firm and solid support, surrounding the orifice of a die, is easily perforated by the punch, which forces out a core into the die, of which the edge aids the sheering, this proves that, to prevent penetration, it is better to place the plate on a soft than on a hard substance. But this conclusion is so palpable an inconsistency, I am sure it must have been inadvertently advanced. This gentleman appears to have read my letters. I wish he would refer to one, in which I describe experiments of the Iron Plate Committee on plates of the same thickness, one back, with three feet of solid oak, and one with a cast-iron block. A 40-pounder smashed the wooden-backed plate into fragments, but made no impression on the iron-backed plate, except a slight indentation less than half an inch deep. On principle this settles the question of rigid *versus* elastic backing, and there really ought to be no more said on the subject; but the men of wood, like the tanner with his leather, are so persistent in *their crotchet*, that I am obliged to reiterate mine, and despite their sarcasm and cavilling, I shall continue to do so, until wood backing is driven out of the field.

Mr. Cheverton makes me smile, in comparing the manipulation of *repoussé* or *embossed silver* to the effect of artillery on iron plates 4 or 5 in. thick. There is no analogy in the cases; the thin plate of precious metal has to be moulded with a delicate tool on a somewhat yielding material, and must not bear on a hard surface. He is not more happy in his reference to displacement. Surely he must know that, weight for weight and strength for strength, much greater displacement can be and is attained in naval architecture with iron plates than with timber. Why this is one of the main advantages of iron over wooden ships, and it is enhanced by the greater amount of stowage room within the frames or timbers.

Oddly, enough, my present antagonist taxes me with not regarding "limits or conditions," whereas I do make limits and conditions, based on the observation of *facts*, which are practical results, the foundation of my arguments. This, my communication to your journal, testify abundantly. If Mr. Cheverton, in his ardent devotion to wood, and his uncompromising advocacy of a theory, has not given himself the trouble to take any cognizance of the various and serious objections to wood backing stated in my letters, I cannot help it. But the fact is, he is guilty himself of the fault he wrongfully imputes to me. He takes no account of "limits and conditions," and convicts himself, as a pure theorist, by deliberately stating that "the question, logically and usefully at issue, is what given thicknesses are the comparative values of iron and wood in the matter of penetration."

Here, then, is the writer's sagacious view of the great naval armour question. Not the fitness of the material either for the construction of the ship or the armour, not the nature or structure of the material as calculated to resist the impact of iron shot and shell, or to avoid combustion, not even the *possibility* of rendering the materials, having regard to their expense as well as their weight, subservient to the required purposes, are to be taken into account; but we are only to consider whether a wall of iron 6 in. thick, or a wall of wood 6 ft. thick will offer the greatest resistance. Verily this is theorizing with a vengeance, and compels me to class the author of so bold a proposition with the enthusiasts of the Mirabeau school, who stand up for a principle at any price. Such a thesis as here advanced might pass muster, if it were of the same vague and slippery nature as "the wave or straight line" theory, which is almost as susceptible of a practical solution as perpetual motion, or squaring the circle. A number of letters on this question, which appeared in the *Mechanics' Magazine*, were read by me with attention until they made my head ache, in a vain attempt to understand the subject, and I gave up the attempt in despair. But the production of iron-cased ships of war is eminently practical, and step by step the best modes of construction, and the best methods, as well as the best material, for rendering the armour shot-proof, can only be determined by experiment. I know no other rule or method, and I must say that a man strongly prejudiced in favour of one material, and an absolute theorist, is not the man to lend a helping hand to the best solution of this question.

I have not taken the pains to refute Mr. Cheverton, and to prove his mistakes, in the hope of converting him, but because the reply to his letter offers the opportunity of thoroughly propounding my ideas on wood backing. I confess to a settled and profound conviction of the immense national importance of that one point as the very root of the question of the invulnerability of ships; and I say now, what I have said many times, that it was a fatal blunder to adopt the plan of fastening the iron cuirass of the "Warrior's," "Minotaur's," and, "Enterprise's" *on wood*—a blunder which it has cost the country millions to commit, and it will cost millions more to remedy.

Mr. Cheverton seems to think that, because he can imagine nothing better than wood, no other backing can be used but wood or iron, and he gives the preference to the former. But, in point of fact, several plans of backing, composed of other materials, and combinations of materials, are under consideration, and will soon be submitted to trial on experimental targets.

Happily the Admiralty is aroused to a sense of the danger into which the iron fleet of the future has drifted, and having shaken off the trammels of the men of wood, it has resolutely determined to enter upon a series of experiments on a liberal scale, with the view of ascertaining whether better modes of constructing naval armour cannot be discovered.

CIVILIAN.

OBSERVATIONS ON THE PROPOSED TELEGRAPH COMMUNICATION BETWEEN IRELAND AND NEWFOUNDLAND.

By Professor William King.

Having under examination the objects obtained from the Irish Atlantic Sea Bed by H.M.S. "Porcupine," of which a "preliminary notice" by myself appeared in the last number of the *Nautical Magazine*,* my attention has been, at the same time, directed to the nature of the Deep Sea Soundings on the West Coast of Ireland, with reference to the establishment of a telegraph connection between this country and Newfoundland.

Before proceeding further, I feel it necessary to state that, previously to entering on a consideration of the latter subject, I held no particular view in favour of any one place for the eastern terminus of the cable. Indeed, I confess to having entertained considerable doubt as to the practicability of successfully carrying a cable across the Atlantic at all.

I also wish it to be understood that I am not writing against any place whatever, for I feel convinced that it will be requisite ultimately to lay down two or more telegraph cables, and probably from different parts of the coast. It becomes my duty, however, on the present occasion, to show that Galway presents, in many points of view, claims which particularly recommend it for selection as one of the stations.

Looking at Mr. Hoskyn's valuable "Report on the Deep Sea Soundings to the Westward of Ireland," and the chart which accompanies it, in the *Nautical Magazine* of the present month, it will be seen that from the Isles of Arran, at the entrance of Galway Bay, there runs out, due west for the distance of 160 miles or more, a gently undulating sea bottom or terrace, having in no place an inclination surpassing that of an ordinary beach. Throughout the entire extent of this terrace the depth of water averages about 100 fathoms, and rarely exceeds 200 fathoms. Near its western termination the terrace is more elevated than elsewhere, except its shore end, giving rise to a flatly-rounded bank, which, in its highest or shallowest part, is little more than 80 fathoms below the surface of the ocean. This elevation, which Mr. Hoskyn has named the Porcupine Bank, appears to extend from the parallel of Cushla Bay, on the south, to that of Innis Boffin, off Connemara, on the north.

At the westernmost edge of the terrace, about fifteen or twenty miles from the shallowest part of the Porcupine Bank, there is, compared with the inclination above mentioned, a rapid descent into deep water, which, however, is not so in reality, being only about 700 fathoms in ten miles. The greatest depth attained in the part alluded to is 1,500 fathoms.

Guided by the maps appended to "Maury's Physical Geography of the Sea" (p. 11) and to Wallich's "North Atlantic Sea Bed," there are grounds for believing that on the parallel of Galway, the last mentioned soundings has gradually continued down to what is termed the "telegraph plateau," a vast submarine plain stretching thence all the way to the banks of Newfoundland, with a pretty uniform depth of about 1,760 fathoms, or two miles.

If the telegraph cable were laid down on the route I have sketched, commencing east of Cushla Bay, which is about 10 miles due west of the town of Galway, and traversing the terrace just described, there is good reason to believe that it would rest on a bottom singularly free from impediments. For the first 160 miles, the bottom consists of calcareous mud and the finest sand, charged for the most part with Polythalamous Foraminifera. In the shallow portion of the terrace forming the Porcupine Bank, the bottom consists of fine and coarsish gravel, with an abundance of shells of various kinds. On the slope which descends to the telegraph plateau, the bottom consists essentially of Monothalamous Foraminifera; and I have no doubt that the same minute organisms and their debris occur spread over the entire plateau, forming a deposit so soft and oozy, that a cable would readily sink into it.

With regard to the bottom, near the landing places, I can only speak of that on the Galway coast. Between the north Isle of Arran and the

* This preliminary notice referred principally to microscopic organisms in the deep sea bed. The writer says:—"The marvellous profusion of *Foraminifera* and other minute structures occurring on the Atlantic sea-bed wherever it descends below the level of a few hundred fathoms, shows that, over a vast portion of the submarine area between Ireland and the United States, there are being formed calcareous deposits analogous to common limestones. While nearly all the particles of these deposits are either the testaceous coverings of dead *Foraminifera* or the impalpable debris of their shells, it is evident that the surface of the Atlantic sea-bed is one vast sheet of the same organisms in a living state, whose office it is to clear the waters of the ocean of all the mineral and organic impurities which are ever flowing into them......Although perforating mollusks are living at great depths, I do not think that there are any grounds for apprehending that they would bore into a telegraph cable. I am also inclined to believe that there is little chance of a cable getting injured if laid down on foraminiferous bottoms; as in such places vital and chemical actions appear to be going on so unceasingly and copiously, that a cable thus circumstanced could not but become covered up in the course of a few years with considerable foraminiferous accumulations."

Skirds there is "foul ground" lying immediately off the proposed landing place. The rocks, judging from those on the adjacent land, are evidently rounded hummocks of syenite and granite, with surfaces worn down by the action of geologically ancient field ice and other glacial agents, such as now prevail in Greenland and in Alpine regions. Instead of being dangerous to a cable, provided it had the ordinary protective coverings, these submarine rocks would probably prove advantageous, inasmuch as they would prevent trawling and line fishing, as well as the anchoring of ships where they prevail.

It is quite possible in laying down the cable to avoid the Porcupine Bank, which, as I have already stated, does not extend south of the parallel of Cushla Bay; but if it should be carried over this bank, no fears need be entertained of the effects of the heavy seas which characterise an Atlantic storm, because, as shown in my "Preliminary Notice," the smallest stones occurring on its suface exhibit appearances of being as little disturbed as if they were at the bottom of a lake. On the other hand, a buoy might be permanently placed on the bank, in proximity to the cable, to indicate where the latter could be found in case of accident; by this means, the repairing of injuries (which I cannot but conceive would be of very rare occurrence) sustained on this side of the Atlantic would be materially expedited.

I may, in passing, remark that the Porcupine Bank is an important feature in favour of making Galway an Atlantic Packet Station. In being the most westerly land-fall on the coast of Ireland, it will enable steamers, during a fog or cloudy weather, to obtain, by soundings, an early intimation of their approach to land, while, both on the north and on the south, no such advantage exists, because the outer edge of the hundred fathoms' terrace, of which the bank is an outlier, treads rapidly towards the land approaching it to within only a distance of from 25 to 50 miles.

If now we refer to the Atlantic sea-bed off the coast of Kerry, it will be found to present features of a different character. Beginning at the coast—say, near Valentia—the bottom slopes down somewhat suddenly to the depth of 525 fathoms; it next rises again, apparently at the same angle, till it reaches a level varying from 195 to 230 fathoms below the surface of the ocean, and where it forms a submarine ridge about 25 miles in width, 140 miles from land, and terminating southward on the parallel of Cape Clear. This ridge, which is evidently a tongue or southern extension of the deepest portion of the terrace lying off Galway, declines rapidly—that is, on its western side—to a depth of from 1,500 to 1,700 fathoms. Further out, the bottom sinks to 2,040 fathoms. Now, if we refer to Maury's map, it will be seen that the last-mentioned soundings, by proceeding to the south, makes that part of the sea-bed where it was obtained a portion of the great 3 miles' deep submarine valley, which was down to the Cape Verd Islands on the coast of Africa, and which, according to the authority cited, actually attains nearly its maximum depth—viz., 2,675 fathoms—somewhere off the south-east coast of Kerry.

Unfortunately, the soundings north of the parallel of Valentia, and near the meridian we are now in, are not sufficiently known, but from the rise of the bottom, as indicated by the two last mentioned soundings, it is to be suspected that the three miles' deep valley gradually rises up to the two-mile deep telegraph plateau, somewhere on the parallel of Loop Head, in Clare. It may possibly extend much farther north, but even in this case it cannot but have lost its distinctive character, and become reduced to a mere trough on the telegraph plateau.

It will now be seen that a telegraph cable, running from any part of Kerry, must, of necessity cross two valleys, the easternmost one upwards of half a mile in depth, and the westernmost, about three miles, before it reaches the Telegraph Plateau. Nothing is known of the western side of the deepest valley, but its eastern side appears to be rocky. The specimen of *Discina*, a shell which lives fixed to stones, rocks, and other objects, mentioned in my "preliminary notice" as having been taken on the east side of the valley, of the depth of 1,240 fathoms, may be regarded as supporting this apprehention.

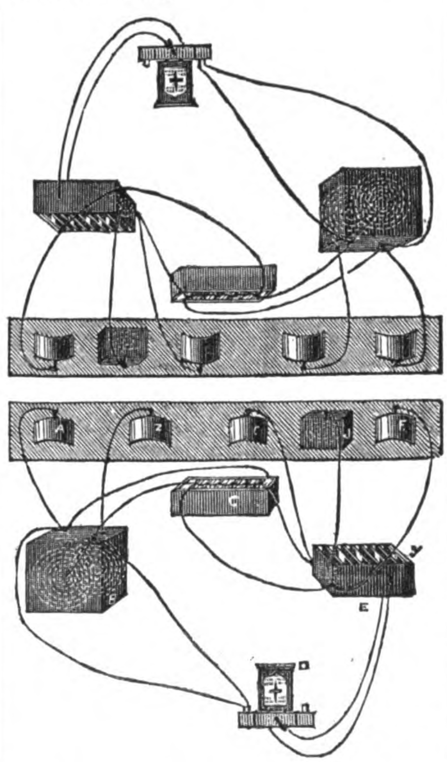
The difficulties attending this route, however, may very possibly be overcome by carefully selecting the course where unfavourable circumstances least prevail, and allowing sufficient length of cable to be payed out, so as it may rest on even portions, not only elevations, but depressions, of the irregularities of the sea-bed.

In conclusion, I may remark that it appears to me, that the conditions most favourable for a telegraph cable between this country and Newfoundland, are a gentle, undulating in-shore bottom, extending far into the Atlantic before attaining any great depth, and its outer edge passing down to the deep telegraph plateau by a not over rapid fall. These conditions can be found nowhere on the coasts of Ireland, except off Galway, where also occurs the Porcupine Bank, the advantages of which have already been stated.

Belmont, near Galway.
November 15th, 1862.

TELEGRAPH APPARATUS FOR SENDING MESSAGES WITHOUT THE USE OF WIRES.

The accompanying engraving represents an arrangement of plates and apparatus for transmitting electric signals and telegraphic messages to distant places without the use of conducting wires or other artificial medium, the invention of Mr. J. Haworth, of Southampton-street, Bloomsbury.



Two plates of metal, one of copper and one of zinc, are buried in the earth. Each separate and distant about one foot from each other, and retained in an upright position and slightly bent so as to form the segment of a cylinder, the axis of which is perpendicular to the surface of the earth. They are buried in such a position as to present their convex sides towards the place to which it is intended to send signals. For a distance of twelve miles and up to seventy-five miles plates of one square foot have been found sufficient. For a distance beyond that up to two hundred miles larger plates are made use of. Two other plates, one of copper G and one of zinc F, in position as shown, each of similar size to plates A and Z and also similarly curved in an upright position, and about two feet distant from each other, with their convex faces also towards the place to which it is intended to send signals. Between these two plates G and F, but not in contact with either plate, is a wooden box marked J, covered with zinc or other material, to preserve it from damp, containing a coil of coated copper wire insulated from the box by shellac or sealing wax poured in a melted state around it. The length and size of the coil found effective has been twelve miles of No. 15 wire.

The plates A and Z are connected, by means of copper wires, to each end of the primary coil fixed in an apparatus B, containing two coils, a primary and a secondary coil, of insulated copper wire, insulated from each other. The length of the primary coil employed is twelve miles of wire No. 15 for experiments, varying from twelve miles up to seventy-five miles; for a distance from seventy-five miles up to two hundred, seventeen miles of primary coil are found sufficient. The coils are about sixteen inches diameter and the primary one about three inches and a half thick, the secondary about one inch and a half.

The internal end of the primary coil is connected by means of a wire to the extreme copper or silver plate of an ordinary galvanic battery C, and the internal end of the secondary coil to the opposite or zinc end of the same battery. The size and power of the battery will depend in some degree upon circumstances, such as the distance to which it is intended to convey the message, the strength and direction of the earth's currents, and even the state of the weather, more power being required in dry than in damp weather. These points must be taken into consideration and allowance made for them.

Similar wires are connected to the same ends of the primary and secondary coils in box B, which are connected with the battery to the binding screws of an ordinary telegraphic indicator D, so as to be capable of being brought into connection with its coil by the motion of the handle.

The ends of the coil surrounding the magnetic needle of D are brought into permanent metallic connection by binding screws, with the condenser or safety valve apparatus E. The condenser consists of glass plates inclosed in a box, with grooves for the plates to slide into. The glass plates are covered with pure gold leaf extending down them about half the way, namely, from the top to the centre, but are insulated from the box by shellac. At one end are two coils, primary and secondary, of insulated gold wire, each coil resembling in shape the form of a watch spring and each insulated from the other by shellac. A ribbon of pure gold is passed alternately over and under the partially covered glass plates so as to be between them all. The extremity of the ribbon is attached to the centre of the secondary coil of gold wire. The outer end of the secondary gold coil is connected with the centre or inner end of the primary coil.

The plates F and G are connected by means of copper wire with the zinc pole of the battery C.

At the point to which it is intended to transmit the message a zinc plate H, and a copper plate Y, similarly curved and similar in size and position, and for similar uses as plates A and Z, already described. The plates H and Y should be buried in the earth with their convex sides towards plates G and F.

Corresponding apparatus are fitted at a distant station: the upper part of the engraving is supposed to represent it, having the plates and batteries buried in the earth in a reverse manner.

On the authority of Mr. James Bruce, marble may be bent or moulded to any required shape by means of a sand-heat, when long continued.

THE MANUFACTURE OF IRON.

At a recent meeting of the Manchester Philosophical Society, Mr. Dyer, Vice-President, exhibited a broken screw bolt, 1¼ in. square (used to fasten a cart body to the axle). The fracture, near the head end, appeared very much like one of cast iron; imbedded in the centre of the bar was a smooth egg-shaped mass about ½ in. diameter, crossing the fracture, and leaving a cavity as its mould in the metal on one side. He assumed that faults like this were pro ably owing to the rapid processes in use for re ucing masses from the puddle into bars of wrought iron, whilst the metal was only partially converted to the malleable state, as appeared in this sample of bad iron. The iron, in a semi-fluid state is passed from the furnace through a succession of rollers, without re-heating or faggoting, as were formerly practised, and at once reduced to the sizes required. The improved rolling mills could not, it seemed, insure improved qualities of wrought iron, whilst they afforded temptations to make it far inferior to any that could have been made fifty years ago. Considering the many hazards to which life and property are exposed in travelling by railway and otherwise, from the iron "shuffled off in haste," and found in use in engineering constructions, it becomes important that previous tests should be employed to ascertain the real nature of the iron, so as to leave no question of its being in a safe condition for the purpose intended, and not like this specimen, and like much now-a-days made by pressing the half-converted puddle into marketable shapes.

In connection wtih the subject of the slow changes which iron undergoes, M. Breguet, of Paris, stated that in their furnace for preparing soft iron he had observed a remarkable case of crystallisation of wrought iron. One of the furnace bars became brittle, and, on breaking a portion of it, he found it to contain a large cubical crystal of iron, each of whose sides measured five millimetres in length. This singular specimen is now in the possesion of M. Balard.

EXPLOSIVE POWDERS.

TO THE EDITOR OF THE "MECHANICS' MAGAZINE."

Sir,—Mr. John Horsley, Esq., F.C.S., analyst for the county of Gloucester, discovered, some years since, that if chlorate of potassa and nut gall, each reduced to a very fine powder, be well compounded, in proportion of three to one, by weight, the product will be violently explosive.

Some experiments recently made, apon a small scale, appeared to show that the best sporting gunpowder gave an impetus of 4, while a like charge of Horsley's powder gave an impetus of 9; so the respective initial velocities were as 4 to 6, and, consequently, the respective percussive force of each was as 16 to 36, or as 1 to 2¼; that is to say, the powder composed of chlorate of potassa and nut gall is 2¼ more violent than the best gunpowder, in small charges; perhaps more so in larger charges.

It should be stated that Horsley's powder explodes at about 450 deg. temperature; and that it can be explodea by *excessive* friction, or by the action of sulphuric acid. It is admirably adapted to the charging of submarine shells, and it may possibly be the thing Mr. Whitworh requires for his projectile shells.

Horsley's powder can be manipulated with much greater ease and safety than common gunpowder, and can be stored as common gunpowder. And, moreover, if the two ingredients be stored together, *unmixed*, no explosion would ensue if the magazine were fired.

John Harvey,
Capt. R.N.

LITERARY PIRACY.

Sir,—The attemps I made, some years ago, to bring the subject of elementary geometry into a more sound and healthy state, both here and in schools, were very ably promoted by the notices which appeared in Nos. 1,175, 1,227, and 1,269, of the Mechanics' Magazine.

In the review of the School Edition, in 1,227, you took occasion to censure the piracy of my book by the then Reverend (but now Right Reverend Bishop) Colenso; and the exposure of his plagiarism had so far effect, that Mr. Colenso did not succeed in his object. It has been a further satisfaction to know that the favourable opinions expressed of my editions of Euclid have lately been followed by the award of a medal by the Jurors of Class 29 of the last International Exhibition, 1862. The Exhibition had scarcely closed, when a plagiarism of my books was published by Messrs. Macmillan at 3s. 6d., entitled a "College and School Euclid, edited by J. Todhunter, M.A., Fellow of St. John's College." I do not hesitate to say, that this is a more manifest wrong doing than that of Mr. Colenso. The latter took only the geometrical exercises, but Mr. Todhunter has besides taken up my manner of arranging the demonstrations, with this difference only, that he begins each step in a vertical line down the margin of the page, and has liberally used my notes. He has printed his book in the same type and style as my university edition. Any one, on comparing the books, could not fail of seeing where Mr. Todhunter has taken the greater part of the materials for making up his book; and of course what he has taken in this way could be purchased at 3s. 6d., a less price than 4s. 6d., the published price of my school edition.

This is not Mr. Todhunter's first attempt at work of this kind: not long since he took largely from Mr. Lund's edition of "Wood's Algebra," for a book on algebra he published. Mr. Lund put forth a pamphlet and remonstrated, pointing out how far Mr. Todhunter had invaded his work. The injustice to Mr. Lund was acknowledged here; but his book was and still is recommended by the College tutors—(I enclose one instance.) But what is more marvellous, the Master and Seniors of his College expressed no censure of his doings, or took any steps to vindicate the right of Mr. Lund, a former Fellow of St. John's College. Perhaps they see no harm in such proceedings, as they have long been practised by Fellows of St. John's College, as you pointed out in page 157 of the No. 1,227 of the Mechanics' Magazine.

I have ventured to bring under your notice this second attempt, under the impression that the general principles of literary honesty are vindicated in your pages, independent of any personal considerations. A foot note in page 41 of No. 1,300 of your Magazine has led me to this opinion, and I feel persuaded that at your hands even-handed justice will be awarded, if you should have time, and feel disposed to institute a comparison of the work of Mr. Todhunter and my own.

I trust I may be pardoned for the liberty I have taken of bringing the subject under your attention, and I remain, Sir,

Yours, &c.,
R. Potts.

Trinity College, Cambridge,
17th Nov., 1862.

PORTABLE SHIPS' PUMPS.

Sir,—In the account of the trial of Portable Ships' Pumps, page 317 of last week's number (copied from the *Times*), there is a slight inaccuracy which I shall be much obliged if you will allow me to rectify.

The report says—"Mr. Stone's pump was of similar dimensions (to mine); but pronounced superior in power and capacity in each of the tests, as to distance, height, &c... The third engine was that of Mr. Gossage, of the Admiralty, and manufactured by Mr. Stone, which underwent the same series of trials as the two named above, with a slight advantage over that of Mr. Roberts."

I beg to observe that my pump was made in October, 1860, expressly to compete with the pump known as Mr. Gorsages; for this purpose I made it as near the same capacity as possible, mine being 326 inches, and Gorsage's 332 inches; the weight of my pump is 2 cwt. 1 qr. 20 lb., and Gorsage's 3 cwt. 2 qr. 7 lb., rather a considerable difference in a machine to be carried about, used in boats, &c.

For some reasons, these trials have been postponed from 1860 until 1862, my pump being ready all the time.

On the 6th inst. my pump was first tried, and delivered 108 gallons with 89½ strokes, being 3½ gallons *more* than due to its capacity. Gossage's, with the same number of men, delivered 107 gallons with 102 strokes, or 14¼ gallons *less* than due to it. In the next trial, with 8 men, my pump delivered 108 gallons with 87½ strokes, being 5¼ gallons *more* than due to it, and Gossage's, with 123 strokes, delivered 110 gallons, or 36¼ *less* than due to it; and with a ⅝ nose pipe my pump delivered 112 gallons with 100 strokes, being 5 gallons less than due to its capacity; and Gossage's, with 158 strokes, delivered 104 gallons only, or 84 *less* than due to its capacity.

In distance, we both threw 67 ft. with ⅝ nose pipe; with ½ do. Gossage could not get any further, but mine threw 75½ ft.; in height there was a still greater difference, my pump throwing the water from 15 to 20 ft. higher in both cases. I think, sir, this proves the *slight advantage* was in my favour.

Mr. Stones pump weighed 3 cwt. 0 qr. 1 lb., and its capacity is 404 in. (about 24 per cent. larger than mine). In the first trial it delivered 110 gallons with 78 strokes, being 3¾ *less* than its due; in the second 109 gallons with 81 strokes, being 9¼ *less*, and with the ⅝ nose pipe it delivered 114 gallons with 85 strokes, being 10 less than due to its capacity; in distance it threw rather further than mine, but did not reach my height. I almost venture to think, sir, in this case also the slight advantage is on my side.

I am, &c.,
Wm. Roberts.

Millwall, Poplar, E.

CORROSION IN BOILER PLATES.

Sir,—Will you allow me to suggest a very simple method of superheating steam, and preventing corrosion in the plates of marine boilers—viz., "by coating the interior surface of the places with two several coats of black oxide of manganese and lamp-black."

Acids have no effect on this composition, while the *manganese decomposes* the muriatic acid of the sea-water, converting it into *chlorine*.

I am, &c.,
James Bruce.

London, Nov. 19.

Meetings for the Week.

Monday.—Royal Geographical Society.—"Latest Explorations in Africa," by Dr. Livingstone, and his brother, Mr. Charles Livingstone, Captains Speke and Grant, Consul Petherick, Captain Baker, R. Moffat, Captain Burton, &c., at 8.30 p.m.

Tuesday.—Institution Civil Engineers.—"The Hownes Gill Viaduct, on the Stockton and Darlington Railway," by Mr. Wm. Cudworth, M.I.C.E., at 8 p.m.

Wednesday.—Society of Arts, at 8 p.m.

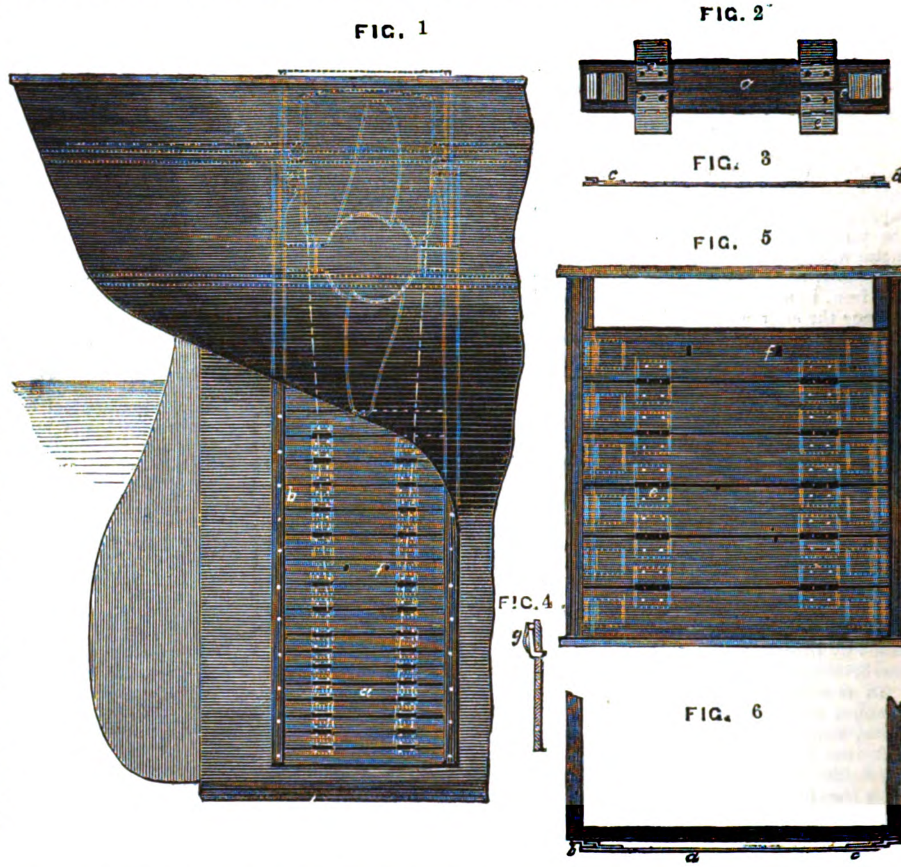
Thursday.—Civil and Mechanical Engineers' Society.—On Coal Gas, by C. Chubb, Esq., at 7.30 p.m.

Bread-making Machines.—On the 2nd of September last, we inserted an extract from a letter by Mr. Edwin Clayton, of Nottingham, giving an account of a bread-making machine, patented by him in 1830. Influenced by his letter, we felt doubtful of the validity of Mr. Steven's patented bread-making machine. On enquiring into the matter, we found that Mr. Clayton's machine consisted of a revolving kneading-trough, with arms to work the dough, which arms have a reverse motion; and that Mr. Steven's patent consists of a fixed trough with revolving knives.

Aluminium Gold.—Most of our readers have heard of aluminium bronze which is a compound of aluminium and copper. This material is likely to be applied in various ways. Messrs. Reid and Co., Newcastle-on-Tyne, have patented its application to watches. It is of golden colour, hard, takes a high polish, and is less liable to scratch than silver or gold.

Means to Prevent the Rotting of Woods.—In order to prevent wooden posts and piles from rotting while in the ground, the following receipt has been sent to the Societé d'Encouragement, Paris. A certain paint is used which has the hardness of stone, which resists damp, and is very cheap. It has been in use for the last five years—50 parts of resin, 40 parts of finely-powdered chalk, about 300 parts of fine hard sand, 4 parts of linseed oil, 1 part of red oxide of lead, and 1 part of sulphuric acid, are mixed together. The resin, chalk, sand, and linseed oil are heated together in an iron boiler; the red lead and the sulphuric acid are then added. They are carefully mixed, and the composition is applied while hot. If it be not found sufficiently fluid, it may be made thinner by adding some more linseed oil. This paint, when cold and dry, forms a varnish of the hardness of stone.

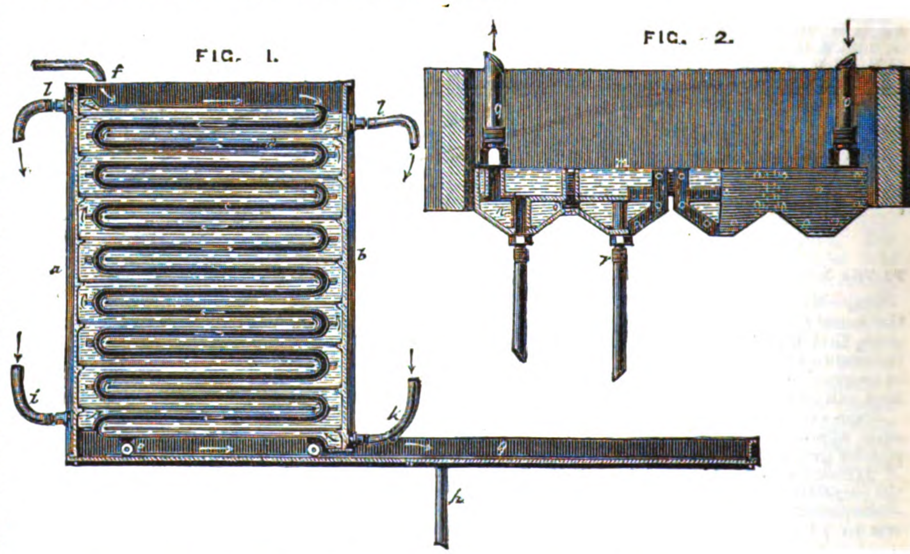
MAJOR-GENERAL HUTCHINSON'S IMPROVEMENT IN SCREW PROPELLER SHIPS.



It is well known that screw steamers lose a great portion of their efficiency as sailing vessels, from the free passage of water through the screw aperture when the screw is raised—especially is that loss apparent when "on a wind," but at all times it increases the difficulty of steering screw ships when under sail, more particularly ships of great length.

The engravings illustrate an arrangement just patented by Major-General Hutchinson, of Plymouth; it consists in filling up the well or space left between the frame or body post and stern-post in ships propelled by a screw, when the screw is raised, by causing plates of metal to slide down in a suitable frame in succession from the deck until the aperture is filled. Fig 1 is a side elevation of the stern of a ship, with the plates *a a* in position, and the screw raised. Each plate *a a* has on its inner sides, lips, or angle pieces, *c c*, as shown at Figs. 2 and 3; these angle pieces form recesses in which guide bars or frame *b b* act. The plates may be hinged together to enable them to be lifted by means of suitable tackle, when desired. The lower plates are shown narrower than the upper ones, to allow of them passing the curvature of the guide bars *b b* at the screw shaft portion of the stern. If it should be found desirable, all the plates may be detached and slid down separately, holes *f f* being provided in each plate to enable its being raised by the hooked catch *g* shown at Fig. 4. Figs. 5 and 6 show a part of the after cabin framing, in which a portion of the plates are stowed when not in use. Both sides of the stern are fitted in the same manner. The column of water between them greatly adds to the stability of both sets, as the water cannot be instantly displaced, and no beams can be pressed inwards by the force of the sea without the corresponding plates on the other side being pressed outwards.

TIZARD'S HEATING AND COOLING APPARATUSES.



The engravings illustrate two apparatuses for heating, cooling, and condensing, the invention of Mr. W. L. Tizard, of Mark-lane. Fig. 1 is a sectional view of an oblong box, containing a number of cellular plates *c c*, piled one above the other, and held together by means of bolts passing through their flanges. To the inside of the casing *a*, a series of partitions are secured; these are so placed as to occupy the spaces in the cellular plates. Another set of partition-plates on a door *b* occupies the spaces in the flanged cellular plates *d d*. The flanges of these plates *d d* are set in a reverse direction to flanges of the plates *c c*. The door is mounted upon small wheels *e e*, to enable its being moved along the rail in the tray *g*, as shown for the purposes of cleaning and repairs. The wort or other material to be heated or cooled is fed by means of the pipe *f* on to the upper cellular-plate from which it passes in a zigzag form, as indicated by the arrows, and falls into the tray *g*, thence by the pipe *h* to any suitable receiver. The water is supplied to the apparatus by the pipes *i*, *k*, and passes out by the pipes *l l*, as indicated.

Fig. 2 shows another arrangement for cooling brewers' worts when they are undergoing vinous fermentation, and also for collecting the yeast. The engraving shows a number of shallow troughs, *m m* having inverted cone-like bottoms *n n*, in communication one with the other by short pipes *o o*; these are supplied with water by the pipe *p*, which issues by the pipe *q*. The troughs *m m* contain the yeast or other liquid to be cooled, and the beer contained in it runs off by the pipes *r r*. The wort troughs may be put in communication with one another by pipes, if desired.

The farmers about Savannah, N.Y., are using six-cent papers of turnip seed as a circulating medium, in the absence of silver. They pass readily among agriculturists. A dollar or two in the medium would be nice in the pocket.

According to some of the Swiss journals, the passage of the Alps by railway on a second point—the Simplon—is in contemplation. A committee of delegates of the Swiss Cantonal Governments have held a conference at Lausanne, where a resolution was come to that a special committee should be named by the Governments of Geneva, Vaud, Friburg, and Valais, in order to come to an understanding with the company having the concession of the Italian line, and to concert on the ways and means for carrying out the plan. The intention is to bore a tunnel, the total length of which is to be from 4,600 to 4,700 metres. The rock to be cut through is easy to be perforated, and is so uniform and solid, the supposition is that it will not require to be faced with any masonry.

A company has just been formed in Greece for cutting through the Isthmus of Corinth, and thus avoiding the long and dangerous coasting of the Peloponnesus. From the earliest times the immense advantage of a canal joining the two seas has been admitted. Nero commenced the work, and traces of it still exist. This latter plan is the one to be now resumed. The width of the canal would be 112 ft., and its depth about 20. Its length would not exceed 3¾ miles. The advantages to navigation to be derived from the cutting of the isthmus are easy to be perceived. For vessels on their way from Marseilles and the Mediterranean to the Piræus the distance would be shortened by 90 miles. The saving of time to vessels coming from the Adriatic would be still more considerable.

SILVER'S SPEED GOVERNORS FOR ENGINES.

FIG. 1.

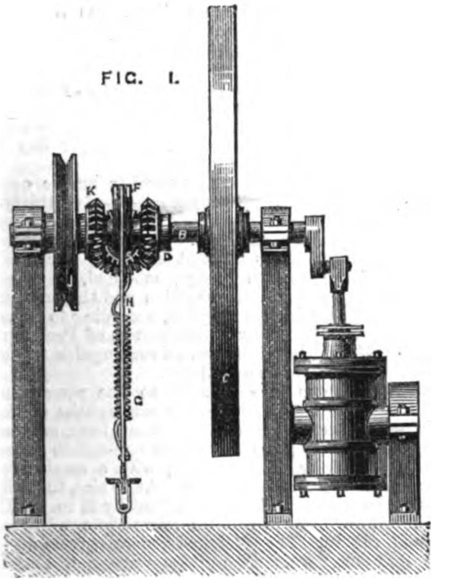


FIG. 2.

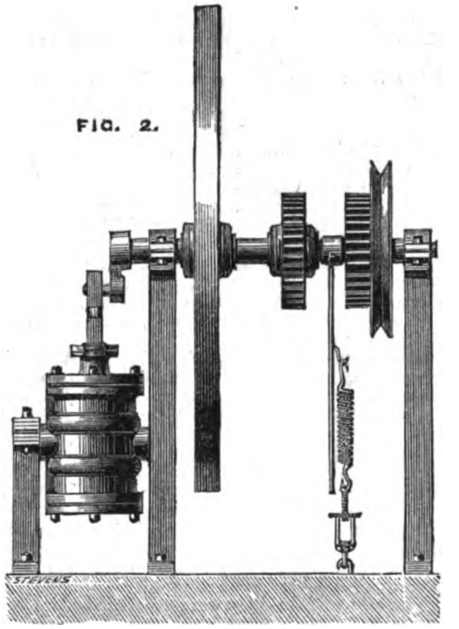

FIG. 3.

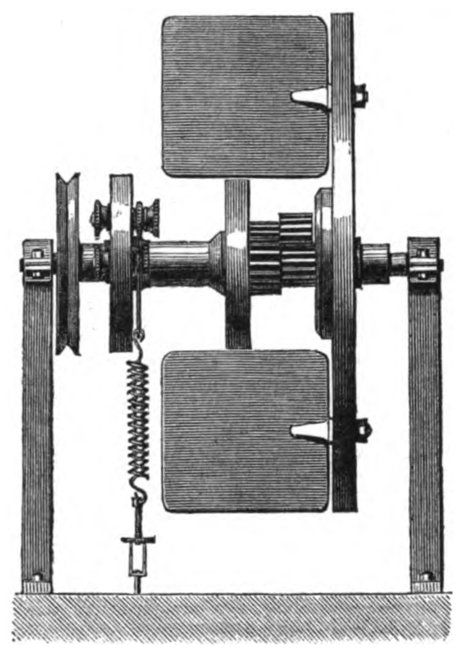

THE above engravings represent three arrangements of governors for regulating the speed of engines, the invention of Mr. T. Silver, of Bury-street, London. Figure 1 is an elevation of a governor, in which an independent engine is made to rotate the horizontal shaft B, upon which the fly wheel C is keyed fast. There is a mitre pinion D keyed to the shaft, and an intermediate pinion E turning loosely on the vibrating arm F. The arm F has an eye or boss, in which, or through which, the shaft B rotates. The one end of the vibrating arm F is shown as connected to a spiral reacting spring G, whilst the opposite end is connected to the throttle valve lever H. The spring G in this case forms no material part of the regulating apparatus, but is employed as a safety spring, being intended for closing the throttle valve in case of any part of the machinery breaking down. The pulley J, or means of receiving the rotatory motion of the main engine, has connected to one face a pinion K gearing with the intermediate pinion E. The pulley J and the pinion K run loosely upon the horizontal shaft B. Thus, upon a difference arising between the speed of rotation of the independent engine and the main engine, the intermediate mitre pinion is made to move around the shaft, and thus act upon the throttle valve.

Fig. 2 exhibits a modification of Fig. 1, by the substitution of spur wheels and pinions instead of bevel wheels, employed for the purpose of taking advantage of the difference of speed between the independent engine and the main engine. The vibrating arm F has two eyes or bosses, one in the centre and the other at one end thereof; the eye at the outer end of the vibrating lever carries a short shaft, one end of which is keyed a spur wheel, and the other a spur pinion. The pulley has a spur pinion upon one face, and they are free to revolve together upon the main shaft or axis.

Fig. 3 exhibits another modification, in which the position of the spur gearing upon the main shaft or spindle is changed, and the fly wheel, which is shown as being fitted with vanes, is not keyed fast upon the shaft, but is free to turn thereon to a limited extent, motion being communicated to the apparatus from the main engine by means of a pulley, wheel, or other gearing; the pinion receiving the motion is keyed upon the main shaft, the retardation offered to the rotation of the fly wheel beyond the velocity to which it is regulated creates a difference between the revolutions of the two parts of the apparatus. Upon such difference arising, the two spur pinions, which are mounted upon a stud projecting from the face of a disc (which is here substituted for the vibrating arm shown in the previous illustrations), is made to travel partially around the spur pinion keyed fast to the main shaft close to the boss of the fly wheel.

Instead of the vibrating arm, two circular discs may be substituted, upon a tube or hollow shaft, the one disc carrying a stud with the spur pinion, and the other having upon the one side a connection with the throttle-valve lever, and on the opposite side a spiral or other spring capable of adjustment. The spring may be attached at any other convenient point, say, the throttle-valve lever, if desired.

Instead of employing spiral springs in the ordinary way, the inventor proposes to employ the re-active force of a metal spring, coiled upon the main or rotating shaft or spindle of the apparatus, one end of such coiled spring being attached to the fly wheel, and the other to the spindle, so that upon any change of motion between the two the spring is caused to coil or uncoil, instead of its expanding or being elongated under strain, and shortening or returning when relieved. When the independent engine is employed to rotate one part of the apparatus, it should be caused to rotate at a higher speed than that of the pulley which receives motion from the main engine.

Proceedings of Societies.

INSTITUTION OF CIVIL ENGINEERS.

NOVEMBER 11, 1862.

JOHN R. M'CLEAN, ESQ., Vice-President, in the Chair.

BEFORE commencing the business of the evening, on this the first meeting of the session, and in the absence of the president, the Chairman said it was his duty to notice the loss the Institution had sustained by the death, during the recess, of two of its most eminent members—Mr. John Edward Errington, vice-president, and Mr. James Walker, past-president.

For upwards of thirty years, and indeed ever since the introduction of the railway system, Mr. Errington occupied a prominent position as an engineer, and, in conjunction with Mr. Locke, executed some of the principal railway works in Great Britain. He was, like his partner, Mr. Locke, a strong advocate for economy in the first cost of construction. By his death the profession had lost one of its most distinguished members, the Institution one of its warmest supporters, and many of us a sincere friend, and one ever ready to afford advice, especially to his numerous pupils and assistants, whose interests it was his constant endeavour to advance. As many of his pupils were actively engaged in the practice of the profession, and had, through his influence, been enabled already to take good positions, the Chairman expressed the hope that they would feel it a duty, no less than a pleasure, incumbent upon them, to communicate plans and descriptions of the works of their eminent masters, and so keep alive the memory of "Locke and Errington" in the Institution of Civil Engineers. Mr. Errington had proved his attachment to the Institution, and his desire to see it prosper, by bequeathing to it the sum of £1,000, free of legacy duty, and without attaching any condition whatever to the gift.

Mr. Walker was one of the oldest members of the profession, having been in active practice as an engineer for upwards of sixty years. He was also one of the earliest members of the Institution, having joined it in the year 1823, and, after the death of Mr. Telford, became its president. For a period of eleven years, during which he so ably conducted its proceedings in that capacity, he was most devoted to its interests, and to his zeal and energy must be greatly attributed the eminent position it held on his retiring from the chair in 1845. Mr. Walker's name was associated with many of the greatest hydraulic works in England and Scotland, including light-houses, harbours, bridges, embankments, and drainage. His opinion was much valued by the elder brethren of the Trinity House, by the Lords of the Admiralty, and by the corporation of the city of London, and it must not be forgotten, especially at the present moment, that twenty years ago he laid down lines for embanking each side of the River Thames, which have never been improved. As the Chairman had had the privilege of being in Mr. Walker's employment for many years prior to 1844, he had an opportunity of knowing his worth, and must express his gratitude for many acts of kindness, and state that it was Mr. Walker's constant endeavour to promote the interests of himself and others. Many members of the profession had also been trained in the same school, including Burges, Bidder, Hawkshaw, Borthwick, and Hartley. During his long and useful career he had secured the admiration and respect of numerous influential friends, as well as the regard of his professional brethren.

The Chairman had much gratification in announcing, that Mr. Walker, having left at Mr. Burges' disposal the twenty-five remaining copies of Telford's "Life and Works," as well as the copyright and copper-plates, Mr. Burges had, in the most handsome and liberal manner, presented them to the institution.

The paper read was on

THE RAILWAY SYSTEM OF GERMANY, by Mr. Robert Crawford, Assoc. Inst. C.E.

It was stated that in Germany, as in England, tramways had formed the germ from which subsequent enterprise developed the vast network of railways now extending throughout the length and breadth of the land. The oldest of these undertakings originated in a 50 years' "privilege," granted by the Austrian Government, upon the 7th September, 1824, for the construction of a line from Budweiss, in Bohemia, to opposite Linz, on the Danube—a distance of upwards of 80 English miles. Subsequently, a concession was obtained for a line from Linz to Gmünden, 42½ miles. The cost of the Budweiss, Linz, and Gmünden line was about £4,877 per mile. The gauge was 3 ft. 7½ in., and it was worked by horses until 1854, when small locomotive engines were employed, first upon a portion of the line, and in the following year upon the entire length.

A proposal to adopt steam as a motive power, instead of horse labour, was carried into effect for the first time in Germany in the case of a railway, 4 miles in length, from Nüremberg to Fürth, which was opened for public traffic on the 7th December, 1835. Thus Germany, possessing at the close of the year 1835, upwards of 108 miles of tramways, had, up to the same time, only 4 miles of railway properly so called. In the five following years, railways were introduced into all parts of the country, so that at the close of 1840, there were twelve railways, either wholly or in part finished, with a total length opened of 377 miles. In the next ten years this had been increased to 4,187 miles; by the close of 1860 to 8,512 miles, and at the end of 1861, a total of 8,866 miles had been constructed, at an average cost of £16,400 per mile. Nearly one-fourth of the entire length was provided with double lines of rails. About 38 per cent. of the existing lines was Government property, 10½ per cent. the property of companies, but worked by Governments, and 51½ per cent. the property of and worked by private or joint-stock companies. Further, it appeared that 93½ per cent. of the entire length was constructed by the different States, 24¾ by companies under a guarantee of interest, or a Government subvention, and 35¼ per cent. by companies at their own cost and risk; so that Government aid had been granted, directly or indirectly, to nearly two-thirds of the entire system. These 8,866 miles of railway comprised 62 different undertakings, as at present constituted, under as many different organisations, and were managed by 19 Government departments and 43 boards of directors.

At the close of the year 1861 Germany had, in addition to the railways, about 143 miles of tramways, constructed at an average cost of £3,200 per mile.

With a view of establishing a common plan of action, and of regulating, to a certain extent, the relations of the different railway companies with each other, a society was formed in the year 1847, under the title of "The Association of Government Railway Directions," which now embraced the whole of the lines, with very unimportant exceptions. Each company subscribed a fixed sum towards the general management fund, together with a variable amount depending upon its length, and was represented at the meetings of the Association and in the debates, in proportion to its importance. A code of laws had been drawn up and agreed to, which was revised from time to time, the rules expressing the decided opinion of the associated body upon all points usually involved in the construction and working of railways. The gauge was now universally throughout the country 4 ft. 8½ in. With regard to curves and gradients the rules laid down were—First, the radius of curvature should, if possible, not be less than 3,600 ft. in level land, nor than 2,000 ft. in hilly districts, except in particular instances, where it might be necessary to reduce it to 1,200 ft., or even, in very rare cases, to 600 ft., but never less. Second, the general scale of maximum gradients admissible on railways was 1 in 200 in level districts, 1 in 100 among hills, and 1 in 40 on mountain lines. Several examples of sharp curves upon works already executed were then noticed. The increased power of locomotive engines had led to a severer character of ruling gradients being introduced than was formerly contemplated, and there were ample proofs in every part of the country, that the limits recognised at present as suitable for the working of locomotives had been reached. Many instances were then given of steep gradients and sharp curves, including a particular account of the Semmering Railway, and the mode of working it. As, however, a description of this railway has been brought before the Institution by Mr. C. R. Drysdale, in the year 1856 (Minutes of Proceedings Inst. C.E., Vol. xv., p. 349), it would suffice to say, that the experience derived from the working of the line went to show, that one of the goods' engines was capable of drawing up the inclines of 1 in 40, at the rate of 9½ miles per hour, a train whose gross weight varied from 100 to 165 tons, according to the state of the rails and of the weather at the time. The ordinary rate of speed was fixed at—

	Ascending. Miles per hour.	Descending. Miles per hour.
For express trains.........	14 1-7	16½
,, ordinary passenger..	11⅝	14 1-7
,, goods, including military transport ...	9⅓	9⅓

The maximum number of trains which had passed over the line in one day was 72, counting both ways. This was during the Italian war. The ordinary number was 27, with from 7 to 8 carriages each. The line was about 25¼ miles in length, was laid with a double way throughout, and had cost £98,270 per mile.

It appeared to be a general, although not a universal plan, in the case of all main lines, to prepare the earthworks and masonry for a double way throughout, but not to lay the second line of rails until the success of the undertaking and the requirements of the traffic demanded it. Some of the heaviest earthworks executed up to the present day were then alludsd to, including one on the Southern State Railway of Bavaria, the greatest height of which was 172 ft., and which contained nearly 3,000,000 cubic yards of material. A list of the largest tunnels on the principal lines was next given.

Viaducts and bridges were treated under two headings:—first, bridges composed altogether of masonry, and second, iron bridges. The views of the Associated Railway Directions on bridge building were:—1st. For bridges, arches of stone or good bricks were preferable to every other description of structure, except in cases which required very oblique bridges. 2nd. Timber bridges were inadmissible. 3rd. When iron bridges were made use of, the portion of the structure which sustained the roadway should consist either of wrought or rolled iron. Thus cast-iron bridges, as well as timber ones, were removed from the field of investigation; the former by negation, and the latter by direct condemnation.

Instances were then adduced and details given of several examples of stone viaducts and bridges of imposing dimensions and extent, including those over the Goeltzsch and the Elser Valleys, on the railway from Leipzig to Hof; and the Neisse viaduct on the railway from Kohlfurth, to Goerlitz, in Prussia. The result of a series of experiments, for the purpose of ascertaining the best description of concrete to be placed round the foundations of the river piers in the latter case, gave the proportions most suitable for yielding a quick setting, hard concrete at 22 per cent. of cement, 22 of sand, and 56 of small broken stones, not exceeding 2 in. diameter. In regard to the bridge over the River Neckar, on the railway from Frankfort-on-Maine to Heidelberg, it was stated that the depth of the keystone was somewhat over the minimum required both by Desjardin's formula and by that of Gauthey; but, on the other hand, it was so out of proportion with the hugh thickness obtained from the method of Perronet, as to prove the total unfitness of this system for calculating cases similar to the one in question. Thus the

	Metres.
Neckar Bridge, as actually built had a depth of key of	1·200
,, according to Gauthey's formula it required	1·125
,, ditto Desjardin's	1·140
,, ditto Perronet's.................................	3·241

In the case of wrought-iron bridges, the arrangement most usually adopted, when the spans were wide, was that of a lattice construction in some one of its various modifications. One of the earliest examples, which was described in detail, was the bridge over the river Kinzig, at Offenburg, on the Baden State Railway, in which it was considered that the arrangement of the material was not judicious, as—1st, The dimensions of the ironwork were uniform throughout the length of the span. 2nd, Although a stronger lattice construction was adopted in the case of the central girder, still the top and bottom sections were of similar dimensions to the outside ones; and, 3rd, The cross sectional area of the iron had not been properly proportioned to its different powers to resist compression and extension, where those forces acted. The bridge over the river Vistula, at Dirschau, on the Eastern Railway of Prussia, was next referred to. It consisted of six spans, each 397 ft. 6 in. in the clear, the depth of the girders being 38 ft. 9 in., and the whole of the material in the superstructure being carefully proportioned to the nature of the strains to which it would be exposed. The Marienberg bridge over the River Nogat, on the same railway, was likewise minutely described. The next examples selected were those over the Rhine, at Cologne, and at Kehl, close to Strasburg; in the latter case the method adopted in constructing the foundations, by means of compressed air, was also mentioned. It was stated that the operation of sinking the foundations progressed at the rate of about 20 ins. per day of twenty-four hours.

In addition, there was also another bridge over the Rhine at Mayence, which consisted of thirty-two openings, having together a clear waterway of 3,134 ft. 6 in. lineal measure. The ironwork in the superstructure was somewhat similarly arranged to that of the Saltash bridge, modified, in some particulars, as to the cross section and the form in which the material was applied, according to what was known in Germany as the system of Professor Pauli, of Munich, which gave a rectangular top to the beam instead of an oval one.

Attention was then directed to the permanent way. It appeared that about seven-eighths of the of the rails in use were of the broad base, or contractor's pattern; the remaining one-eighth being composed chiefly of chair rails, with a small proportion of bridge-shaped ones. As to size, the rails were not less than 4½ in. in height by 2¼ in. width of head, and the surface was curved to a radius of from 5 to 7 in. They weighed generally from 66 to 76 lbs. per yard. Fish-plates were now almost universally adopted for connecting the ends of the rails, and the joints were always supported by a sleeper; a wrought-iron chair being interposed between the rail and the timber. Recently, a trial had been made of the modern English system of leaving the joint free without any sleeper under it, and the result had been so satisfactory, that it was intended to extend it. The almost universal system of supports was that of cross-sleepers. They were of oak, where it could be procured at a reasonable price; but different descriptions of larch and fir were often used, after being prepared by some chemical process to resist the tendency to decay.

The quantity and description of rolling stock in use on different railways in Northern and Southern Germany varied greatly; but as nearly as could be estimated, at the close of the year 1861, there were—

Locomotive engines	0·414	per English mile.
Passenger carriages, average 41·8 seats each	0·807	,,
Goods trucks, average load 6·9 tons	7·040	,,

Before any engine was permitted to be used its boiler must be tested with hydraurie pressure to at least one and a half times the maximum steam pressure, which it was intended to sustain, and a similar test must be applied after the engine had run its first 46,109 miles, and be subsequently repeated every time an additional 36,887 miles had been made. The rate of speed was usually, for express trains, from 27 to 35 miles an hour, for ordinary passenger trains from 20 to 25 miles, and goods train from 10 to 15 miles per hour, in each case exclusive of stoppages.

It was adnounced that the discussion, which had been commenced, would be continued at the next meeting, Tuesday, November 18th.

INSTITUTION OF MECHANICAL ENGINEERS.

THE general meeting of the members of this Institution was held on Thursday, the 6th instant, at the house of the Institution, Newhall-street, Birmingham; Charles F. Beyer, Esq., in the chair.

The secretary, Mr. W. P. Marshall, having read the minutes of the previous meeting, a number of new members were elected; and the officers of the Institution were nominated for the next annual election.

The first paper read was, "On a Packing for Pistons of Steam Engines and Pumps," by Mr. George M. Miller, of Dublin, which consists of two packing rings fitted into grooves in the piston, and pressed outwards against the cylinder by the pressure of the steam in steam-engine pistons, without the use of any springs. The steam is admitted behind the packing rings by two small holes opening from each face of the piston into the bottom of the nearest groove, whereby each ring in

turn is pressed steam-tight against the cylinder by the steam acting alternately on the opposite sides of the piston. Only one ring is thus in action at the same time, and when the steam is shut off the piston is free to move without any friction. The packing rings are of steel or brass, put into the grooves in the piston without any spring, the ends of the rings being made generally a simple butt joint at the division, and sometimes with a lapped or a tongued joint. These steam-packed pistons have been used for several years in the locomotives of the Great Southern and Western Railway of Ireland, and have proved thoroughly satisfactory and advantageous, the engines having run between 30,000 and 40,000 miles on an average with the brass or steel packing rings, before the rings required renewal, while one set of steel rings ran upwards of 90,000 miles before the rings were worn out; the cylinders have a highly polished surface, and their wear is found to be very slight. The same packing rings have been employed for some years with equal advantage in stationary engines with vertical cylinders. They have also been used for some years for pump buckets, the rings in this case being pressed outwards against the cylinder by the pressure of the water admitted behind them in the same manner as in the steam pistons; and the same plan of packing has also been applied to the gland packing of a pump plunger, the packing rings being in that case pressed inwards upon the plunger by the pressure of water round the outside of the rings. Specimens were exhibited of the steel and brass packing rings taken from the pistons of locomotive and stationary engines; and also of a pump bucket with brass packing ring that had been working constantly for more than two years.

The next paper was "On Machinery for the Manufacture of Gun Stocks," by Mr. Thomas Greenwood, of Leeds, giving a description of the entire series of operations that are performed by a set of machines for shaping and finishing the stocks for rifles. The whole number of successive operations is 23, each advancing the stock a step further from the original rough bar of wood towards its completion in the required form, as illustrated by a complete set of the stocks that was exhibited from each stage of the manufacture. Throughout the machinery the principle is carried out of copying the required shape from a pattern, by means of cutters revolving at a high speed, and guided by a tracer that follows the pattern. A detailed description was given of the lock-bedding machine, for cutting and shaping the recess in the stock to contain the gun-lock: and also of one of the cutting machines employed at a later stage for shaping a portion of the stock beyond the lock; and the two machines were exhibited to the meeting in complete working order. In the lock-bedding machine, five separate operations are successively performed to cut and shape the recess for the lock, with one fixing of the stock in the machine. The five cutters or drills are carried each on a vertical spindle mounted in a circular cage, which turns round loose on the centre vertical driving shaft of the machine; a plain cylindrical driving wheel on the top of the driving shaft drives each of the five drills by friction, by means of a small driving roller on the top of the drill spindle. The drill spindle is carried in a slide capable of being moved by a handle both vertically and horizontally round the circumference of the cage, and the gun stock is fixed on a horizontal slide below, moved longitudinally by a second handle; and by the combination of these three movements the lock recess is cut out in the stock by the drills, a steel pattern being fixed alongside the gun stock, which is followed by a tracer fixed parallel to the drill in the slide that carries the drill spindle. The five drills are all of different sizes, for cutting the different portions of the recess, and each drill is accompanied with a corresponding tracer of the same size. When one drill has finished its own particular portion of the work, the circular cage is turned round to bring the next drill into operation upon the stock. In the second machine shown, the contour of the stock is obtained from a cam of the required pattern, and the revolving cutter shaft is mounted in a rocking lever, the extremity of which is the tracer that follows the circumference of the pattern cam. The gun stock is fixed horizontally in the machine underneath the cam shaft and parallel to it; and the stock, together with the cam shaft, is turned slowly round by a hand wheel, while the cutters are brought up by a treadle. The cutters are set at a little inclination to the stock, so as to cut the wood with a paring-action and produce a smooth surface. In both the machines the gun stock that is being operated upon is bedded closely upon a fixed cylindrical bar that exactly corresponds with the barrel of the gun, and fits precisely in the groove made for it in the stock in one of the earlier operations; and this barrel groove serves as the fixed accurate basis for all the subsequent operations, insuring absolute identity in all the stocks. The other machines of the series are similar in the principles of construction, differing merely in the details of arrangement for performing the special operation intended. By the employment of machinery in this manner, strict accuracy of work is obtainad, and all the separate portions of the gun are interchangeable with any gun stock.

The last paper was a "Description of a Hydraulic Shears and Punch," by Mr. James Tangye, of Birmingham, consisting of a simple arrangement of hydraulic press in a compact and portable form, applied to the purposes of shearing and punching iron bars. In the shears, the upper shear blade is fixed in the frame of the machine, and the lower shear blade is carried on the top of the ram of the press cylinder, which forms the bottom of the machine, the water being pumped in by a small force pump worked by a hand lever. For enabling the water to escape from the press cylinder in lowering the shears after shearing a piece of work, the hand lever is depressed beyond the ordinary working limit, until a projection on the bottom of the plunger presses open the delivery valve, allowing the water to flow back from the press into the cistern. In the punch, the press cylinder is placed at the top and inverted, the ram carrying the punch. This hydraulic shears and punch afford the means of shearing and punching railway rails or bars of large section by the power of one man only at the hand lever; in shearing rails the shear blades are shaped to the form of the rail, so as to cut shear through the entire section at once and make a clean cut. The same construction of force pump and press is also applied as a portable hydraulic lifting jack, the ram of the press forming the foot on which the jack stands, while the cylinder is inverted and rises; the reservoir of water is contained in the head of the jack, from which the water is pumped by the force pump into the cylinder for raising the load, whereby a load of as much as sixty tons can be lifted by the power of one man with a portable jack. Specimens of the hydraulic lifting jack were exhibited, and also specimens of rails and bars sheared and punched.

The meeting then terminated.

Gossip.

New York papers, received by the last mail, contain an account of the trial trip of the "Paissac" turret battery, built on the plan of the "Monitor," carrying two guns in her turret, one of 11 in., and the other of 15 in. bore, the latter being the largest piece of ordnance that has yet been mounted on board any vessel. The following are the dimensions of the "Paissac's" monster gun:—Maximum diameter, 48 in; minimum ditto (rough), 38 in.; minimum ditto (finished), 26½ in.; bore, 15 in. The length of the gun is 13 ft. 7 in.; the weight of rough casting, 68,000 lb.; of the finished gun, 42,000 lb.; of the solid shot, 460 lb.; and of the shell, 330 lb. The maximum or service charge of powder is 35 lb. The speed attained by the "Paissac" on her trial trip was only five knots.

It is proposed to supersede the use of armour plates for ships by willow-wood of the thickness of a foot, having a steel rolled plate of one inch and a half inserted in the middle of the wood. This wood has the property of resisting compression to a great degree, and possesses the same cohesive and repulsive properties of steel. Whalebone, from its cohesion and tenacity, has likewise been proposed as an extra backing for the iron plates, placing the same between the iron and the teak or willow. Horn has its advocates as an additional backing.

The Great Eastern Railway Company will apply next session for powers to construct a line from its existing system, at March, to Spalding, on the loop line of the Great Northern, and from that point to obtain running powers over the Great Northern to Askerne. This is the "coal line" of last session, but it is brought forward in a modified form, so as to avoid the opposition which would otherwise be experienced from the Great Northern.

At the last meeting of the Manchester Scientific Society, Dr. Roberts exhibited some microscopic preparation illustrating the effect of a solution of magenta on the blood. The red blood-discs were tinted of a faint rose; and one portion of their outline, in a majority of the corpuscles, appeared more deeply tinted than the remainder. The pale corpuscles were more strongly tinted than the red; and their nuclei were displayed with great clearness, dyed of a magnificent carbuncle-red. A number of the nuclei were seen in the process of division, more or less advanced, and in some cells the partition had issued in the production of two, three, or four distinct secondary nuclei. There was evidence that these secondary nuclei were set free in the blood, and, by subsequent enlargement and change of form and chemical constitution, developed into red blood discs, which would therefore appear to be, as Mr. Wharton Jones first conceived, free cellæform nuclei, and not, according to the current belief, enlarged and altered pale corpuscles.

The tunneling of the Alps is being continued with great activity. It is expected that the actual advance of 3·8 metres every twenty-four hours will be carried up to 5·6 m., or even 6 m., so that, unless some unexpected accident should occur, the work will be finished in 1870. Some fears have arisen about insufficient ventilation of the tunnel, when finished; Engineers, however, fear there will be too much air. The two ends of the tunnel have a difference of level of 131 metres; they will, therefore, never be at the same temperature, and a current of air will thus continually traverse the tunnel.

ABESTOS PAPER.—In the Northern States of America abestos is found in rather large quantities, in fine, long, silky threads. The low price of this mineral, its power of resisting heat, and its low heat-conducting power, have led to experiments for using it in paper-making. This paper contains about one-third in weight of abestos. The paper burns with a flame, and leaves a white residue, which keeps the shape of the sheet if carefully handled. Any writing in common ink is perceptible even after the organic substance of the paper is consumed.

MALLEABE IRON NAILS.—Besides the very extensively employed machine-made nails, there is another description of nails getting into use, especially for fixing tiles on to the roofs of factories and similar buildings. These are nails of cast malleable iron. They oxydize much less in damp air than common iron nails, or even copper ones. To manufacture them, very hot metal is run into ordinary sand moulds. These malleable iron nails are very brittle before being placed in the annealing furnace. Their sojourn in the furnace renders them very ductile. They are then put into polishing barrels, in which they are cleaned, whereupon they are thrown into a zinc bath to obtain a coating. In a former number we alluded to a machine in the Exhibition for casting nails.

Patents for Inventions.

ABRIDGED SPECIFICATIONS OF PATENTS.

THE Abridged Specifications of Patents given below are classified, according to the subjects to which the respective inventions refer, in the following Table. By the system of classification adopted, the numerical and chronological order of the specifications is preserved, and combined with all the advantages of a division into classes. It should be understood that these abridgements are prepared exclusively for this Magazine from official copies supplied by the Government, and are therefore the property of the Proprietors of this Magazine. Other Papers are hereby warned not to produce them without an acknowledgement:—

1157. A. MARKS. *Improvements in artificial feathers, applicable to certain ornaments of dress.* Dated April 21, 1862.

This invention consists in employing, for the above purpose, goose and swan feathers, either separately or in combination, in such manner as to admit of being sewn, or otherwise held together, through the medium of a stalk or stem, and, subsequently, shaped and finished as required, the said feather being previously cleansed and rendered soft and fit for being coloured, curled, or otherwise embellished. *Patent abandoned.*

1158. E. F. CLARKE. *Improvements in propellers for steam ships and other vessels.* Dated April 21, 1862.

This invention relates, firstly, to an improvement in the screw propeller. The inventor makes or constructs the boss of a semi-spherical form, preferably much larger than it has hitherto been made, and passes the driving shaft into or through it in the ordinary way. The flat side of such semi-spherical boss works against a smooth disc, or other smooth surface, fitted to or made part of the false stern post, of the same diameter as the boss; and the driving shaft trunk, to obviate resistance as a ship or vessel passes through the water, is enlarged, or made of about equal diameter, by which means, and the cutting off of the leading edges of the blades, which are cast with, or fitted to, the above-mentioned boss as at present, the trail of "dead water" and vibration will be prevented. The invention relates, secondly, to propelling apparatus, to be used in lieu of paddle and other side propellers. Instead of carrying ont the main shaft after it passses the hull of a vessel in a straight line, it is forged or fitted with a number of cranks, by preference three on each side, similar to the cranks used for working a set of three pumps. Parallel to the main shaft, and of the same form, the inventor places one or several crank shafts, resting on bearings fitted in or on the sides of the ship, and across to and on framework carried out for that purpose. Each set of cranks is coupled to connecting rods, which carry one or more floats, so jointed that they will "feather" out of the water at the turn of the stroke, and prevent back water, the motion being somewhat similar, where one float is used, to that adopted by the Indians in paddling a canoe, and where several are used, they move together like louvre boards. *Patent abandoned.*

1159. R. A. BROOMAN. *Improvements in packets or protectors for covering metal and other surfaces, to prevent loss of heat by radiation.* (A communication.) Dated April 21, 1862.

This invention consists in the employment of cords, bands, or fabrics composed of bristles or hairs, or of a packing of bristles or hairs, in their natural state, with which the surfaces are covered or surrounded on the outside. These materially will be found economical and durable, and do not readily carbonise. For protecting cylinders and cylindrical bodies the inventor uses ropes or bands of any kind of hair or bristles. For flat or irregular surfaces he makes the hairs or bristles into a woven or felted fabric, and fastens the fabric on such surfaces. *Patent completed.*

1160. F. TOLHAUSEN. *An improvement in horse shoes.* (A communication.) Dated April 21 1862.

This improvement in horse shoes relates to the means for rendering horses less liable to slip when the ground has become slippery by frost or from other causes. For this purpose the inventor provides in the horse shoe a suitable number of holes that are tapped and are intended to receive screw-points—that is to say, conical or pyramidal spikes, having a screwed portion and a square for screwing them into the horse shoe by means of a screw-key. These points can be taken out or removed in summer time, or when the ground is not slippery, and in that case he prefers filling the screw-holes by means of screws, the heads of which come flush with the horse shoe. *Patent abandoned.*

1161. T. ATTWOOD. *Improvements in kitcheners.* Dated April 21, 1862.

According to this invention the patentee makes the oven door in two parts, and so arranges the fittings, that, when open, the doors stand at right angles with the front. On the insides of the door he forms ledges or rests, which, with the doors in the open position above mentioned, are in a direct line with the ledges or rests of the oven, and in such manner that, when the doors are so open, they form a continuous slide on which the tray or shelf on which the meat or anything that may be cooking is placed can be drawn out of the oven for the purposes of basting, flowering, changing, or otherwise, which can thus be carried on with the greatest possible facility. An oven, furnished with one door only, might also be so fitted to enable which he projects a sliding piece on the opposite side of the shelf or plate sufficiently far behind to support that side of the plate when it is drawn out. The second part of the invention relates to a new mode of construction of the oven, which consists in making the lower flue stop and the bottom plate of the oven of one and the same piece of metal, which affords a greater amount of conduction of heat to the bottom of the oven, consequently, the desideratum of a greater amonnt of bottom heat is obtained. The third part of the invention relates to making the fire-door simply to slide, instead of being hung with hinges as usual. For this purpose he constructs and fits the fire-door to the kitchener so as to slide laterally behind the front plate of the boiler. This is a great advantage, both when such door is used as a regulator, and for roasting in front of the boiler. *Patent completed.*

1162. C. CALLEBAUT. *Improvements in sewing machines.* Dated April 21, 1862.

These improvements are applicable to shuttle-sewing machines, and the first part of the invention consists in the construction of a frame or mechanism for sewing transversally and longitudinally at option by means of a shaft placed underneath the machine; this frame forms one with the drawing hook or claw, and receives its motion from two cams fixed to the shaft working the shuttle; by pushing forward a lever for changing its action to the right and left, one of these cams is placed in communication with the frame, a double spring moved by the lever presses on the frame in a transverse and longitudinal direction, and two screws serve to regulate the length of the stitch in either direction. The second part of the invention consists in an ungearing or reversing mechanism, which the patentee applies to the shaft working the drawer, in order to change the direction of the drawing mechanism, and cause the stuff to return on itself to produce the superposed or stop stitches. This ungearing or reversing mechanism consists of a bevel-wheel, on each side of which is set another bevel wheel, the two latter being mounted on a horizontal driving shaft; this shaft is formed with a groove to allow of the said wheels sliding longitudinally, one of the cog wheels only gearing with that of the drawing mechanism; or a clutch may be used for reversing the motion. The driving shaft turns always in the same direction. If by means of a lever or handle one of the wheels on the shaft be put in communication with the wheel which puts the drawing mechanism in motion, the direction of rotation of the latter will be deterred, and the article to be sewn will be allowed to return on itself. The third part of the invention consists in replacing the handle or crank of the shuttle by a pinion wheel, catching into a wheel carrying a cam, which at each two stitches gives motion to the drawing hook or claw in a transversal direction, when the machine is set up for sewing in a longitudinal direction. He obtains by this means the lock stitch. *Patent completed.*

1163. A. DIXON. *Improvements in knife and fork cleaning machines.* Dated April 21, 1862.

We cannot here quote the voluminous details of this invention. *Patent abandoned.*

1164. J. C. AMOS. *An improved mode of, and improvements in, apparatus for supplying surface condensers with water, part of which improvements is applicable to blowers and rotary pumps generally.* Dated April 21, 1862.

The object of this invention is, first, to provide a ready access to the fan or impeller of rotary pumps, particularly when applied to the injection of water into surface condensers, and also when required to the fans of blowers. In the application of rotary pumps or impellers on ship-board, and also on land, the space that can be afforded them is frequently very limited, and great difficulty has therefore been found in providing means for removing the fan and working parts for examination and repair, the construction of the fan case (when not divided down the middle), requiring space to be left on both sides—on one side for the removal of the bonnet of the case, and on the other for giving the fan axle an end-way motion. The patentee now proposes to form the case in such manner that the mere removal of the cover will allow of the removal of the fan together with its axle and bearing. *Patent completed.*

1165. C. C. CREEKE. *Improvements in the construction of drain and other pipes.* Dated April 21, 1862.

In carryng out this invention the patentee moulds the pipes so that their ends shall lock the one into the other and draw tightly together. The sockets and flanges which he employs may vary in form, so as to present either one or two abutting surfaces; but in all cases he moulds these ends of the pipes with wedge-shaped projections and recesses, which, by an axial motion being given to one of the pipes, shall serve to draw the ends of the pipes together, and make a secure joint, preserving, however, until the joint has hardened the elasticity referred to. Before thus securing the pipes he inserts a suitable packing or cement between the abutting surfaces, and he also lubricates the entire surface of the socket and its counterpart, by which means, when the pipes are laid in place and screwed up, water or gas-tight joints will be secured. *Patent completed.*

1166. T. LEA and S. SMITH. *Improvements in burglary alarms or indicators.* Dated April 22, 1862.

According to this invention, upon a door, window, or similar moveable body, of or in a house or building, being attempted to be forced or opened, the same will be notified by an indicator which will at once indicate in what room or place this has happened, the same arrangements being in connection with arrangements for sounding an alarm or alarum, and for causing a match to strike against a friction lighter or striker, also for turning on a gas light, to be lighted by the said match, or for lighting a candle where gas is not available. *Patent completed.*

1167. E. H. C. MONCKTON. *Improvements in umbrellas, parasols, awnings, tents, and covering clothes, and in water-proofing the same.* Dated April 22, 1862.

The first process constituting part of this invention consists in passing the fabrics through a solution of wax and resin in hot oils of any description, and thence through or between rollers which, while expressing the greater part of the hot solution, will leave a sufficient portion thereof to render the fabric water or rain proof. The second process consists in the additions of so utions of gums and resins to oil and wax, melted together and applied as described. The third process consists in steeping the fabrics in a strong solution of soap and water, to which alum is then to be added till precipitation ceases, and subjecting it to pressure, by rolling or otherwise, so as to incorporate the soap and alum into the body of the cloth; the cloth, when dry, will be found to be for the most part waterproof; where additional security is desired, it must be further treated, as described. *Patent completed.*

1168. S. S. PUTMAN. *Certain improvements in machines for forging horse-shoe nails and other articles.* Dated April 22, 1862.

This invention cannot be described without reference to the drawings. *Patent completed.*

1169. C. E. ELLIOTT. *Improvements in the preparation of dried yeast.* (A communication.) Dated April 22, 1862.

For this purpose fresh thick sub-fermentative yeast is taken and stirred up with twelve times as much water, and it is then drained through a cloth used as a sieve into a clean vessel; it must be allowed then to settle well, and the water has then to be poured off. The sediment is again mixed with water, and the same operation is again twice repeated. After the third draining a beautiful white yeast is found as a sediment at the bottom of the vessel. This latter sediment is then to be stirred up with some purified carbonate of soda or potash, and rectified spirit, using ⅓ of an ounce of alkali to one pound of sediment, and ⅔ of an ounce of rectified spirit, and is then left to stand quietly for half an hour, and afterwards is poured into sacks and pressed dry. Half an ounce of gelatine is then added to every two pounds of yeast; the gelatine is boiled into a solid mass, and is mixed after it has become almost cold, first, with one pound of yeast, after proper kneading is thoroughly mixed with the other pound of yeast, and is rolled into a stick, which is then exposed for from ten to twelve hours to a cold temperature. After the lapse of this period the union has taken place perfectly, the stick is unrolled and cut with a glass knife into any form desired, and the pieces themselves are dried on frames covered with a cloth in an ordinary temperature. *Patent abandoned.*

1170. C. WEBSTER. *Improvements in self-acting fountains, adapted for garden-engines, fire-engines, and for raising and forcing water from mines, wells, and other places.* Dated April 22, 1862.

This invention consists in so constructing and arranging certain parts of self-acting fountains, and of charging such parts with compressed air, as to render the raising and forcing of the water from a reservoir contained in said fountains self-acting and continuous, according to the size of the reservoir. *Patent abandoned.*

1171. A. WARNER. *Improvements in the construction of vessels of war and in floating or other batteries.* Dated April 22, 1862.

The patentee prefers to form the outer skin of a plate or plates of iron of sufficient thickness to resist the action of ordinary shot or shell, and between this outer metal skin and the planking or timbers of the ship, or battery, he forms chambers or cells by the arrangement of the metal or timbers which support or form the outer skin, and these chambers or cells he afterwards fills up with molten metal, or with other materials cemented together, so as to form a solid and compact mass. *Patent completed.*

1172. J. H. JOHNSON. *Improvements in apparatus for propelling and manœuvring.* (A communication.) Dated April 22, 1862.

This relates to a peculiar mode of applying and actuating screw propellers, whereby greater command of the ship is obtained as regards steering, and the drifting on to a lee shore prevented. The inventor proposes to mount the axis of the propeller in a moveable frame, placed at the stern of the ship, and capable of turning through the half of a circle, so as to bring the propeller shaft at any desired angle with the keel. This frame may be turned by the usual means, or by other mechanical arrangements. The propeller shaft derives its motion by the aid of suitable bevel or other gearing from a vertical shaft, which forms the turning pivot of the frame, and this shaft receives its motion from the ordinary propeller shaft contained inside the ship through the intervention of a pair of bevel wheels. *Patent abandoned.*

1173. G. SCOVILLE. *Improvements in pistons for steam-engines.* (A communication.) Dated April 22, 1862.

The object here is to simplify and perfect the use and application of metallic packing for pistons of steam-engines, and to dispense with the use of springs or other mechanical contrivances for adjusting and regulating such packing. The packing rings are kept expanded against the inside of the cylinder by the pressure of the steam, instead of by springs. *Patent completed.*

1174. R. BOBY. *Improvements in the construction of apparatus for rolling or crushing land.* Dated April 22, 1862.

In carrying out this invention the axle tree on which the roller or rollers, or pressing wheels, are mounted, turns in properly lubricated bearings or grease boxes at each end of the frame, so that it may rotate therein with as little friction as possible. If the roller or clod crusher be composed of two or more parts or pressing surfaces, one or more of the parts or wheels may, if desired, be permanently or temporarily attached to the axle tree or spindle by ratchet wedges or other contrivances. The axle tree or spindle will be obliged to burn in its bearings, but the ratchet attachments of the rollers will allow the latter, when passing round curves, or when the implement is being turned round at the end of the field, to turn back or rotate on the spindle. By this arrangement the friction of the working parts will be reduced to a mimimum, and the power required for drawing the implement over the land will be lessened. The bracket ends or arms of the roller frame are provided with bushes or pairs of bearings, so that should any part be worn away, the damaged part may be removed and replaced by a second part. *Patent completed.*

1175. R. JINKS. *Improvements in apparatus for suspending, raising, and lowering venetian blinds, and for retaining them, and other blinds, and also curtains and sun shades, at any required height.* Dated April 23, 1862.

This consists in suspending venetian blinds by tapes or ribbons fixed to and winding round a roller, and in making such roller of less circumference in the parts where the tapes are fixed than in that part to which is fixed, and round which passes the cord used for causing the roller to revolve. Or in suspending the blind as aforesaid from a roller, made as described, or of uniform thickness throughout, which is made to revolve by a cord fixed to and passing round a wheel or reel of greater circumference than the roller and attached to the end of it, the object being to obtain leverage by passing the cord used to draw up or lower the blind round a greater circumference than that round which the tapes or ribbons pass. So far as the invention relates to apparatus for retaining venetian and other blinds, &c., at any required length, it consists in using an improved trigger and rack. *Patent abandoned.*

1176. L. HOLDEN. *Certain improvements in harness for animals of draught and burden.* Dated April 23, 1862.

This invention is not described apart from the drawings. *Patent abandoned.*

1177. W. MOIR. *An improved instrument for ascertaining the specific gravity of liquids.* Dated April 23, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1178. G. N. BATES. *Improvements in dressing lace and other fabrics.* Dated April 23, 1862.

The patentee claims the use for the above purpose of an amalgamation or combination of bees'-wax and gelatine, or of an agent produced by combining or amalgamating bees'-wax or sperm-wax with gelatine. *Patent completed.*

1179. G. H. BIRKBECK. *Improvements in lubricating apparatus.* (A communication.) Dated April 23, 1862.

This consists in so arranging apparatus that a sufficient quantity of oil is constantly supplied to lubricate the parts required, whilst they are in motion, the supply of oil ceasing whilst they are at rest. The apparatus is also so arranged that any excess of oil raised thereby, at once flows back into the oil vessel, without being deteriorated by coming in contact with the moving frictional surfaces. *Patent completed.*

1180. W. CARPENTER. *An improved method of printing in colours.* Dated April 23, 1862.

This consists in an improved method of printing in colours in cases where four colours, and where from four to twenty-four varieties or transpositions of these colours may be required, with ordinary presses or machines from one form or surface, and with one making ready only. To work this method, the patentee divides the matter into four parts, making them up to one gauge, and imposes or places the said sections or parts in any desired way, provided only that the same relative corner of each shall point towards the centre of the whole form or surface to be printed from, equal space being left between each section or part. After making ready, he works all the sheets required in one colour; he then turns the sheets round in any direction, and works them in a second colour, when he turns them again and works in a third colour, and then again for a fourth colour, thus obtaining four varieties of the design of four colours in each. If the whole number of varieties, viz., twenty-four, be required, nothing more is needed than to turn a portion of the sheets in the second, third, and fourth positions before working them in the second colour, and the same for the third colour, and finish them in the only remaining position in the fourth colour, thus producing six kinds of sheets of four varieties on each, or twenty-four single varieties of four colours in each. *Patent completed.*

1181. J. PRICE. *Improvements in spikes for railways and other purposes, and in the mode of manufacturing and securing the same.* Dated April 23, 1862.

This consists in making an ordinary solid spike or pin, and then splitting it longitudinally for a greater or less portion of its length by a circular saw or shears. When the material to be used in the spike is a softer metal, such as copper or white metal, the inventor proposes to form the spike either by having it cast with the split and bevelled points, or by the process above described. The two limbs or halves thus formed are bevelled inwards at the point, which causes their opening or separation when driven into the sleeper or other timber. In order, however, to insure with greater certainty, the opening of the split end of the spike or pin, he proposes to use a small iron, metal, or hard wood, wedge, cone, pyramid, plug, or ball, which is dropped into or inserted in the hole to receive the spike, which hole is to be bored to about the depth to which the solid portion of the spike will reach when driven home, and upon which the bevelled end of the spike is driven, such wedge or cone serving effectually to open or separate the split. *Patent abandoned.*

1182. A. ROBERTSON and R. BARTER. *Improvements in apparatus for distributing and projecting fluids either for surgical, sanatory, or domestic purposes.* Dated April 23, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1183. W. FEAR, JUN. *Improved arrangements for joining the saw-plates of veneer and other saws constructed in segments.* Dated April 23, 1862.

Where the edge of one saw plate abuts against the other, the inventor makes an orifice, part of which is through one plate and the other part through the other; into this orifice he fits a copper or other suitable bolt, which is passed into the orifice, and then the thin end is flattened out, so as to rivet and secure the bolt firmly in its place, whereby any two abutting plates are kept fast held together, and the ends of the rivet may be made flush with the surface of the saw-plate or other plate, and will in wear always keep flush. *Patent abandoned.*

1184. A. HODGKINSON. *A mixture or composition to be used in the process of boiling, preparing, or bleaching vegetable substances, whether they are in the manufactured or unmanufactured state, which mixture may also be used in the manufacture of soap.* Dated April 23, 1862.

This consists of any oil or distillation of wood or coal, or stone, or petroleum or rock oil, or paraffine, in combination with lime or caustic soda, or common soda-ash. The patentee proposes to use the oil in the proportion of one to one and a half or two gallons, in combination with any of the above alkalis, in a solution of a strength or density to stand from two to four degrees of Twaddle's hydrometer, varying the strength according to the quality of the fabric to be operated upon. The mixture may be used as a soap if required, or it may be added to the alkaline, rosin, and fatty matters ordinarily used in the manufacture of soap.—*Patent completed.*

1185. J. H. JOHNSON. *Improvements in apparatus for taking deep sea soundings, and for recording the speed of ships.* (A communication.) Dated April 23, 1862.

This consists in the use for that purpose of a set of revolving screw blades, which are connected with the indicating mechanism by a suitable ratchet coupling, so as to be held in gear therewith when descending to the bottom in taking soundings, or when being drawn through the water, when used as a log, by the resistence of the water itself, and thrown out of gear by concussion upon the bottom or by the resistance of the water when ascending, thus allowing the blades to turn without moving the indicating apparatus during the raising of the apparatus. The details of the invention are voluminous.—*Patent completed.*

1186. G. T. BOUSFIELD. *Improvements in the construction of elliptic springs for wheel carriages and other purposes.* (A communication.) Dated April 23, 1862.

The patentee claims the combination of the arched leaves of a spring, with an arched tie bar, substantially as set forth. Also the combination of the arched spring leaves and arched tie bar by a head on the tie bar, against the shoulder of which the end of the adjacent spring leaf abuts, substantially as described. Also the combination of two sets of spring leaves, and two tie bars, by a clasp embracing the adjacent heads of the tie bars, substantially as set forth. Also the combination of the spring tie bar and spring leaves, so that the spring leaves may be flexed a certain distance before the pressure is propagated to the tie bar to extend it longitudinally, substantially as set forth. *Patent completed.*

1187. A. V. NEWTON. *Improvements in looms for manufacturing tufted pile fabrics, and in the mode of operating such looms.* (A communication.) Dated April 23, 1862.

This relates to a previous patent, dated 17th May, 1856 (No. 2434), and consists, firstly, in an improvement in the manner of mounting the warps in the loom, and in the operation of the harness, whereby the tufts are more effectually secured in the fabric, and a better web or back produced than can be effected by the loom described in the specification of the patent above mentioned. Secondly, In an improvement in the mechanism for transferring one by one the frames which carry the spools on which the tufting yarns are wound of the various colours required for each range of tufts in the design or figure to be woven. Thirdly, in an improvement which may be denominated the combing operation. Fourthly, In an improvement in the mechanism for cutting off the tufts from the yarns on the spools, by which that operation is rendered more perfect and the mechanism simplified. And, lastly, in an improvement by which the chafing of the warps experienced in the use of the loom is prevented. *Patent completed.*

1188. W. E. NEWTON. *An improved fertilising composition.* (A communication.) Dated April 23, 1862.

This new fertilising composition is composed of animal charcoal, sulphuric acid, and liquid animal matter, in certain proportions. *Patent completed.*

1189. W. E. NEWTON. *Improvements in the manufacture of imitation lace, net, or openwork fabrics.* (A communication.) Dated April 23, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1190. C. E. HEINKE. *Improvements in diving helmets, dresses, and apparatus, parts of which improvements may be also employed for extinguishing fires in ships and other confined places.* Dated April 23, 1862.

This relates, first, to the pump, and consists in constructing it as a three-throw pump, for supplying air to divers, the several parts being so arranged as to throw or force air and water at the same time, but through distinct and different hose. It also consists in increasing the depth of the breast-plate, so that it may cover the chest and the region of the lungs, so as to protect the lungs from the heavy pressure of the water. The boots are made of canvas, coated with india-rubber. *Patent completed.*

1191. J. ENDEAN. *Improvements in cocks, taps, and valves.* Dated April 24, 1862.

This consists in the following arrangement of parts:—A duct, or ducts, is or are formed with a cock, tap, or valve-shank, as it is termed, having a chamber or valve-box, provided with a solid or partially solid enlargement of the said duct or ducts, of conical or conoidial form, with the requisite apertures therein, and upon this conical or conoidial part is fitted a hollow cone or conoid correspondent thereto, provided also with apertures communicating with the ducts and ways, adapted so that the steam, gas, water, or fluid will enter the valve-box or chamber, pass over or against the said hollow cone or conoid, and out at the outlet or outlets, this hollow cone or conoid being provided with a stem, spindle, or handle, passing through the chamber or valve-box aforesaid, whereby the hollow cone or connoid may be turned, so as to bring the aperture therein upon, to, or away from the apertures in the aforesaid enlargement of the duct or ducts, and thus open and shut the same, as desired. The patentee arranges the apertures that the inlet shall never be closed and hence the hollow cone or conoid shall always be kept held to its seat with an equal pressure on its centre surface. *Patent completed.*

1192. W. HAGGETT. *Improvements in locomotive engines and carriages for railways, part of which improvements are applicable to carriages and vehicles for train and common roads.* Dated April 25, 1862.

The documents relating to this invention cannot, at present, be seen, an extension of time for filing the final specification having been petitioned for.

1193. H. WHEATLEY. *Improvements in or applicable to the employment of steam for heating or drying purposes* Dated April 24, 1862.

The patentee claims the application and use of a pump for drawing off the condensed water or steam from steam piping, and returning the same to the boiler or steam generator, or to be used for other purposes. *Patent completed.*

1194. J. BOND. *Certain improvements in projectiles, which improvements are applicable to horns attached to vessels for war purposes* Dated April 24, 1862.

These improvements are principally adapted to projectiles for smooth-bored guns, but they can also be efficiently used in rifled barrels. In performing the invention, the projectile is cylindrical and elongated, and the forward end is recessed to receive a charge of fulminating or other exploding powder, and a plug, either with a percussion cap or not. The body of metal around the ecess forms a punch, which penetrates with facility the armour plates or other body against which the projectile strikes, and when the projectile has peneteated to a certain depth, which can be regulated by the shape and position of the plug, the projectile explodes and enlarges the hole. In using the projectile for smooth-bored firearms and ordnance, a taper plug is used, and the projectiles are made with diagonal grooves. In applying these improvements to the horns of vessels for war purposes, the exterihr plug may be dispensed with, and the recess containing the charge must be hermetically closed in any convenient way. *Patent completed.*

1195. W. D. RUCK. *The manufacture of grease from coal tar, coal oil, creosote, or dead oil.* Dated April 24, 1862.

This consists in obtaining a certain grease from coal tar, coal oil, creosote, or dead oil. The inventor takes either of these, and treats it with sulphuric or other suitable acid. He heats it, and runs it into cold water. It is to be well stirred, and the grease then forms in lumps at the bottom of the vessel in which it is so treated. The grease is to be pressed to extract the water from it. It is then suitable for lubricating purposes, and also for candle making, when mixed with other substances. *Patent abandoned.*

1196. J. WINSBORROW. *Improvements in wet gas meters.* Dated April 24, 1862.

The object here is to facilitate and render more uniform the supply of gas by wet gas meters. For this purpose the inlet valve, in place of being applied direct to the float, is attached to it by leverage, so that when the float rises and falls a short distance, the distance of motion of the valve is increased in proportion to the difference in the length of leverage employed. The float moves in a chamber sealed above the water line from the inlet valve, so as to have gaseous communication only with the measured gas chamber. *Patent completed.*

1197. G. DAVIES. *Improvements in the manufacture of matting and in apparatus for the same.* Dated April 24, 1862.

The patentee claims, first, the manufacture of mats or malling of coir, having the pile or cut surface raised from strands or warps placed parallel with the warp of the backing or foundation, as described. Secondly, the arrangement of parts described, combined with a loom for weaving coir mats for the purpose of receiving and operating threads or strands introduced in the warp for the production of the pile as described. *Patent completed.*

1198. J. A. TRAVERSIER. *Improvements in making ladies' bonnets.* Dated April 24, 1862.

Here the body of the bonnet is composed of metallic wire for supporting the material forming the front and back of the bonnet; this wire is united to hinged and spring branches, so as to support the bonnet and form it according to the fashion. These spring branches allow of opening and closing the bonnet. When closed it takes up little space, and is able to retake its form instantaneously. The bonnet is provided with a pin to keep the bonnet on the head. *Patent abandoned..*

1199. J. F. ALLEN. *Improvements in slide valves and value gear for steam engines.* Dated April 24, 1862.

The nature of this invention consists, 1, In the use of a valve which, in that form of it which is adapted to perform only the single office of admitting or of releasing the steam, has a cavity in the face, and in that form which is adapted to perform the double office of admitting and releasing the steam, has a passage over the cup, which valve, moving on a seat of corresponding form, uncovers at the same time two openings for the passage of the steam into one part. In steam engines it is desirable to uncover a large area of steam port or passage by a slight movement of the valve, especially at that part of its movement where it is commencing to uncover the port or passage, and also to close the same as quickly as possible, whereby in the case of admitting and cutting off the steam, the wasteful effects of wire drawing are, in a great measure, avoided, and, in exhausting, speedy release is attained. *Patent completed.*

1200. G. W. BELDING. *Improvements in harrows or cultivators.* (A communication.) Dated April 24, 1862.

This relates to the teeth of harrows. Both single and double frames are employed for adapting the implement to a variety of soils and uses. The double frame consists of three pieces of suitable dimensions; the two outside pieces which in use diverge from the centre piece, are made adjustable, and may be brought parallel for convenience of transportation and storing. The drawing power is applied to the centre piece, and to this is fixed the front tooth. The single frame consists of one straight piece, to which is fixed one row of teeth only. This frame is drawn by an arm attached to the centre of the harrow or cultivator, and carried forward more or less diverging from the body of the implement, according to the depth of cultivation required. The teeth are constructed with broad thin coulters descending in a backward direction for the purpose of cutting the sod, and also to prevent their clogging. To the back and lower end of each coulter is attached a mould board. The lower edge of the coulter extends slightly below the mould, so as to raise the implement over stones or other obstrnctions when in motion, and also to protect the teeth from injury. The teeth in both frames are similar in shape, with the exception of the front tooth of the double implement, which is constructed with two mould boards or diverging wings. The front tooth turn furrows outward in opposite directions, while the succeeding teeth turn the furrows inward. In the single frame the teeth which are fixed obliquely, in reference to the length of the implements, and nearly in a line with the arm, all turn furrows in one direction, leaving the land perfectly smooth. *Patent abandoned.*

1201. F. DANGERFIELD. *Improvements in lithographic or zincographic presses.* Dated April 24, 1862.

The patentee claims placing the printing cylinder over, and the scraper box under, the bed, which is made to turn over, to move to and fro, and to receive pressure from the scraper by bolts acting against an eccentric or cam, as described. *Patent completed.*

1202. R. MUSHET. *An improvement or improvements in the lining, repairing, or fettling of puddling furnaces.* Dated April 24, 1862.

This consists in employing that refractory ore of litanium, called ilmenite, for lining, repairing, or fettling the sides of the puddling furnace, in order the better to enable the sides of the said furnace to withstand the action of the iron, slag, or cinder generated during the puddling process. "Bull dog," or hematite iron ore may be used in mixture with ilmenite for "fettling" puddling furnaces according to this invention, but the additton of these substances ("bull dog" iron and hematite iron ore to ilmenite for

repairing or fettling the puddling furnace) is not essential to the success of the invention. *Patent completed.*

1203. J. OFFORD. *Improvements in carriages.* Dated April 24, 1862.

Here the inventor improves the wheels by constructing the nave, stock, or centre part of wrought iron, forged whole, bored, and hardened, so as to prevent the necessity for a separate axle-box, and tapped so as to receive the spokes, which he also makes of wrought iron or other metal, and screws into the nave. In forming the felloes or rim of the wheel, he introduces a laminated principle of construction, using wood, vulcanite, india-rubber, and iron or steel, or other suitable material. The invention also comprises improvements in the steps of carriages, whereby more space is afforded for the foot, and the step rendered self-acting and noiseless. *Patent abandoned.*

1204. R. ZIMARA. *Improvements in stoves for heating and ventilating buildings.* Dated April 24, 1862.

One of the principal objects of these improvements in stoves is so to construct and arrange the flues and air passages thereof, that the air in its passage to the interior of the building may be heated by pressing through a series of pipes or passages composed entirely of earthenware. *Patent completed.*

1205. J. W. ASHBY. *Improved apparatus for obtaining motive power from the wind.* (A communication.) Dated April 24, 1862.

Here a shaft is mounted (at a suitable elevation) vertically on a foot step, and secured at its upper end by means of stay rods or ropes, attached to a collar in which the shaft is free to turn. Mounted horizontally on this shaft is a series of cross arms, which are intended to receive sails that are to be spread on skeleton frames attached to the opposite extremities of the several arms. These arms are arranged in pairs, and there may be one, two, or more pairs set one above the other at suitable distances apart to allow of the wind acting freely upon them. The cross arms are so mounted that they are free to receive an axial motion to the extent of about 45°, in order to yield to the pressure of the wind. The cross arms of each pair are mounted so as to cross each other at right angles, and the skeleton frames of each cross arm are fixed so as to be at an angle of about 45°. Thus the pressure of the wind upon that sail which is presented to the wind, will cause it to take a vertical position, and present its head surface to the breeze, and at the same moment the position of its corresponding sail will be shifted so as to present the least possible resistance thereto: *Patent abandoned.*

1206. S. C. SALISBURY, *Improvements in the construction of sewing-machines.* Dated April 25, 1862.

The chief object of this invention is to manufacture sewing-machines that shall be equal to heavy work, such as boot-sewing and the sewing of coarse clothing. To avoid the vibration which attends the working of machines with a revolving lever or levers, for operating the vertical needle and presser foot, the inventor proposes to employ a novel combination of parts, which enables him to work the needle and presser, and also the shuttle, from cams on the driving shaft, which shaft is mounted above the table of the machine. The cam shaft is mounted in a hollow bracket arm, and carries at its extremity a compound cam. A groove in this cam receives a bowle from the pendant arm of a crank lever, which has its fulcrum on the bracket arm. The other arm of this lever is connected by a link to the vertical needle bar, and through this arrangement the vertical movements of the needle are obtained. A second crank-lever, mounted on the bracket arm, and set at right angles to the first-mentioned lever, is operated by the inner face of the cam, and, while reciprocating, it strikes on the under side of a pin projecting from the stem of the presser, and lifts the same from the work. A spring, as usual, serves to return the presser to its pressed position. The feed motion is effected by a cam projection on the outer end of the cam, acting upon one end of a rock lever, the other end of which carries a pin that bears upon the inner edge of the presser foot stem. Every rotation, therefore, of the cam-shaft will impart a rocking motion to the presser foot, and thereby effect the feed of the cloth up to the vertical needle. For taking up the slack thread, he employs a swinging arm pendant from the vertical needle guide-box, through the end of which the thread is passed on its way to the eye of the needle. A crank-pin on the end of the cam-shaft gives this arm a movement outwards at the moment the slack is made, and thus the slack thread is drawn on one side. *Patent abandoned.*

1207. F. BARNETT. *Improved electric danger signals for railways and other cognate purposes.* Dated April 25, 1862.

Here it is arranged that, between all stations on railways, there shall be on each side of the line (for the up and down trains) tall posts erected, surrounded by round balls, or other shaped signals, to work in grooves, and be sustained in their places each by a catch connected with a galvanic pile or battery. The communication between the said pile or battery, and the moveable ball or other shaped signal, shall be at the station on either side of the said post or posts supporting each a moveable ball, or other suitable signal, of whatever shape, by which connection the person at the station, or elsewhere, in charge, will be able, by completing the circuit of electricity, to cause these moveable signals to fall, at the distance of many miles, from the upper to the lower part of the groove on the signal post; this, during the day, giving abundant notice to drivers to arrive cautiously and avoid collisions. For night signals, the inventor proposes that the same, or other similar tall signal posts, shall be surmounted by electric lamps, having the half only clear facing the arriving train, and the other half dark, to avoid misleading trains coming in an opposite direction. *Patent abandoned.*

1208. G. RICHARDS. *Improvements in ordnance and the manner of loading such with the charges and projectiles suitable thereto.* Dated April 25, 1862.

This invention consists, firstly, in an improved method of rifling guns, in order to give a greater initial velocity to projectiles than has hitherto been given by the system of rifling at present in use. This improved rifling consists of two or more projections or rails (instead of grooves) upon the inner surface or bore of the piece, the shape of which projections the patentee at present prefers to be that resembling an U in cross section. It consists, secondly, in improvements in the method of loading ordnance, as follows:—The cannon is to be perforated or pierced at the breech; the loading and sponging are to be effected by a metal rod, wire, or rope, passing through the perforation and thence to the muzzle; the charge is to be entered at the muzzle and drawn by the rod wire or rope into the chamber of the gun, and there discontinued, when necessary, in readiness for firing; the sponge is also to be entered at the muzzle. The breech is furnished with a revolving disc, segment of disc, or other stopper for closing the perforation when required. The perforation may ultimately be used as a "touch hole," and the stopper may be used as a cutter to sever the wire or rope when either of the latter is used in loading. The invention refers, thirdly, to the charges and projectiles suitable to this invention. He prefers at present to make the cartridges for the improved method of loading with a central longitudinal perforation, through which the loading rod passes and is connected with the face of the shot or sabot; they may also be made with indentations at the sides to take the rifling. The method of connecting the loading rod with the shot or sabot, at present, is by means of a screw, and also a shot and stud similar to a bayonet catch. *Patent completed.*

1209. J. F. BRUNET. *Improvements in the manufacture of fringes.* (A communication.) Dated April 25, 1862.

This relates to the fixing or consolidating the twist of fingers by caloric action, and to improveed machinery for making the twist. The machinery used consists of a reciprocating sliding carriage, working on a bed, and holding another sliding carriage in a manner similar to a compound slide rest. *Patent abandoned.*

1210. R. C. MANSELL. *Improvements in the construction of wheels to be used on railways.* Dated April 25, 1862.

This consists in making certain combinations of grooved, filleted, or flanged tyres, in connection with grooved, filleted, or flanged plates or rings for securing the tyres on to the bodies of wheels, and preventing the said tyres flying off in the event of their breakage, and grooved, rivetted, and flanged rims of wheels and other appliances in connection therewith. In making these combinations the patentee uses the securing plates or rings in connection with the tyres and rims of wheels, and also with the tyres only, and he makes the tyre or tyres and rims with a groove in, or fillet, or flange, on either one or both of their sides, and he makes the securing plates or rings of any form in cross section that may be required to fit the section of the grooves in, or fillets or projections on the tyres, or in or on the tyres and rims of wheels, so as to grasp the same. *Patent completed.*

1211. P. R. DRUMMOND. *A revolving rake.* Dated April 25, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1212. J. T. DAVIES. *Improvements in circuit horse powers.* (A communication.) Dated April 25, 1852.

This invention is not described apart from the drawings. *Patent abandoned.*

1213. R. P. ROBERTS. *Improvements in the preparation of paper for copying letters and other documents, and in the preparation of copying ink.* Dated April 25, 1862.

Here the inventor impregnates the paper with a material which, when a document written in ink is pressed against, will be acted on by the ink, and thus produce a copy of the writing. The material employed for this purpose is glycerine, or glycerine together with tannin or oxalic acid, or glycerine together with sub-carbonate of potash, or glycerine together with tannin and sub-carbonate of potash. The paper, after having had these materials applied to it, may be made into books, and letters, &c., may be copied upon it by placing the letters on the paper and pressing the book in a press. The improvement in copying ink consists in combining glycerine, molasses, and the seeds known as albamoschus with ink making materials. *Patent abandoned.*

1214. J. ELDER. *Improvements in steam-engines and boilers.* Dated April 25, 1862.

This invention relates to improvements in steam-engines of the class known as "Randolph, Elder and Company's combined cylinder engines," and to improvements in steam-boilers suitable for the same, and for other kinds of steam-engines. A first improvement in the engines consists in constructing and arranging the valves, ports, and passages between each low pressure cylinder, and the high pressure cylinder, so that when the valve is admitting steam from the latter to the former, only a comparatively small amount of admission opening (one port for example) is uncovered, whilst the same travel of the valve in the opposite direction will put a comparatively large amount of opening (one or more parts for example) in communication with the exhaust passage. A second improvement relates to the modification of valve gearing in use with the same class of engines, wherein the eccentrics mounted on a separate shaft, or on a tubular shaft, are reversed by the action of spiral grooves or feathers on such shaft on moving it longitudinally. A third improvement relates to the working of four cylinders when arranged to act in pairs on cranks at different angles. Hitherto two of such cylinders have received steam direct from the boiler, the other two receiving the steam which has already acted in the first two. According to the present improvement, however, but which is designed only for steam of very high original pressure, the steam from the boiler works in one cylinder and then in a second, from which it is made to pass into a chamber wherein it may or may not be superheated. From this chamber it is next made to pass into and work in the third cylinder, and finally works in the fourth one, from which it passes to the condenser. A fourth improvement relates to the design or arrangement of the parts of four-cylinder engines combined with surface condensers. The improvements in steam-boilers are applicable to the class of boiler in which the fire gases act directly upon a series of tubes containing the water, and they consist in arranging the tubing and other parts, and in applying apparatus in such a way that the water may circulate through the tubing in a downward direction, the opposite to the direction of the fire gases. *Patent completed.*

1215. J. SHAW. *Improvements in steam and other power engines and indicators.* (A communication.) Dated April 25, 1862.

This consists, 1, in certain improvements in the arrangement of equilibrium valves for the admission of steam to the cylinder, and in similar valves for its egress, rendering the same more efficient for the economical working of steam, especially when used in conjunction with the equilibrium and flexible piston described; 2, in an equilibrium and flexible piston that may be run with safety with little clearance in the cylinder ends, avoiding thereby a considerable amount of the loss of steam now caused by this clearance; 3, in governing apparatus of great compactness and sensitiveness, capable of being arranged so as to act as a speed indicator, applied to an eqilibrium valve, in which certain improvements are made to greatly reduce the friction of its working parts, such apparatus being applicable alike to stationary, moveable, and marine engines, whether worked by steam, air, gas, or water, by which the speed of such engines may be kept at any required rate, though they be subjected to great variations of load. *Patent completed.*

1216. J. ASPINALL. *An improved apparatus for the safe conveyance from sea to land of ship's papers, documents, money, and other valuables when wrecks or other casualties occur at sea* Dated April 25, 1862.

This consists of various thicknesses of cork fastened together, through the centre of which an aperture is made sufficiently large to receive a water-tight brass or other metal tube or vessel, which is to be inserted and fixed therein, the mouth of the tube or vessel being enclosed with a cap, which is to be secured thereon, so as to secure any letters or papers, or valuable articles, in the tube. The cork is enclosed in a case of sheet copper, zinc, or other metal, and to the exterior of this case a brass plate may be soldered, or otheswise secured, on which the name of the ship, owner, &c., may be stamped. These buoys may be of various sizes and shapes. *Patent completed.*

1217. C. REED. *A new method of treating the sorghum saccharatum or holcus saccharatus in order to obtain saccharine liquor and pulp therefrom.* Dated April 25, 1862.

This invention consists in taking the plant, after it has been cut, and in passing it between rollers, or in subjecting it to pressure in a hydraulic, or other suitable press, to express the juice and partially prepare the fibre. After the juice has been expressed, or the dry plant may be taken unpressed, the plant is cut, subjected to a boiling caustic alkali, is bleached, and converted into pulp in a pulping engine. The juice expressed may be evaporated and converted into sugar, or it may be distilled to produce a spirit either process being performed in the ordinary manner of sugar making and distilling. *Patent abandoned.*

1218. A. C. KIRK. *Improvements in refrigerating apparatus.* Dated April 25, 1862.

This relates to a peculiar arrangement and combination of apparatus for producing cold by the alternate compression and expansion of air, or any inconsiderable and elastic gas, and consists in alternately compressing and expanding the air or gas in a vessel having a moveable piston, and provided with a suitable regenerator, through which, on the piston being moved to one end of the vessel, the enclosed air may pass freely to the other end, giving out its heat or absorbing heat from the regenerator as it passes through it. The piston is caused to move so that the air, whilst being compressed, will always be at one end of the vessel, which the patentee calls the hot end, and, whilst being expanded, will be always at the opposite or cold end of the same, the regenerator preventing the conveyance of heat or cold from one end of the vessel to the other. The heat generated during compression is removed by exposing that part of the vessel to a current of cold air, water, or other cooling medium, whilst the cold produced at the other end by expansion is used to refrigerate any liquid or substance which may be brought in contact therewith. *Patent completed.*

1219. A. APPLEGARTH. *Improvements in printing in colours, and in apparatus to be employed for this purpose.* Dated April 25, 1862.

For the purpose of printing a sheet in several colours, the inventor fixes the paper, or material to be printed, in a frame which holds securely the edges, and it may be other parts of the sheet. In printing he employs a number of such frames, they are entirely separate from the printing press, and have the sheets placed in them by hand labour. The frames are all made of exactly the same length and breadth. The series of printing blocks (one for each colour) are arranged truly in a straight line or lines, one behind the other, and their distances apart are made accurately to correspond. The frames, containing the sheets to be printed, are laid in succession on the bed of the press, and they are kept against a guide rail thereon, so that they may be accurately one behind the other, and the last frame of the series is pressed up to a stop at the end of the bed. In printing, the series of blocks arranged as above described, one behind the other, are brought in contact with the corresponding series of frames containing the sheets to be printed, and each block prints its own colour; then the end frame of the series is removed, and the remaining frames are pushed on until they are stopped by the stop at the end of the bed, a fresh frame being introduced at the commencement of the series. The blocks then produce another series of impressions, each sheet being there printed with two colours, which it will be seen will exactly register the one with the other. In this manner the work goes on, the sheets being impressed in succession with each of the colours, and this being done the frames containing them are removed at the end of the series. *Patent abandoned.*

1220. W. HALE. *Improvements in rockets.* Dated April 25, 1862.

The object of these improvements is to insure a more correct line of light and longer range in the employment of war rockets than can be obtained by any other arrangement hitherto made use of, and also to effect a rapid rotation in

the rocket without having any of its power subtracted for that purpose, so that the whole power of the gas shall be exerted in giving the onward motion, whereas in the patentee's former improvements in rockets one-third of the whole power is devoted to the exclusive purpose of effecting rotation, and but two-thirds of producing the onward motion. He accomplishes this improvement by screwing three tubes into the cast iron end piece of the tail of the rocket, in lines parallel to its longitudinal axis, at equal distances from each other, around a central aperture, from which tubes and central aperture the gas, when generated in the rocket, escapes freely and direct; and as these openings are all parallel with each other, and in the direction of the rocket's longitudinal axis, the whole force of the gas in its escape acts to impel the rocket forward. He produces a rapid rotation at the same time without the necessity of having tangential apertures or inclined planes for the gas to imfring on (as he required in his former patents for effecting rotation) by simply cutting away from each of the three tubes that project from the tail piece one-half of the side, for the purpose of allowing the gas, as it escapes in its compressed state, to expand on one side of each tube in a direction that makes a tangent to the circle in which the tubes are placed, while on the opposite side it is prevented from expanding by the half tubes that remain, thus producing an unbalanced pressure, which causes the rocket to rotate rapidly about its longitudinal axis; or, instead of screwing the tubes into the tail piece, the half tubes and the central apertures may be formed with the tail piece in one casting, which plan he very much prefers. *Patent completed.*

1221. W. FISKEN. *Improved apparatus for cultivating land by means of steam power.* Dated April 25, 1862.

This invention relates to the employment of two progressive combined anchor windlasses for hauling ploughs and other implements of tillage. An anchor and windlass are combined in one frame, and one of these combined anchor windlasses is placed at each end or side of the field to be cultivated in the line of the traverse of the plough, or other cultivating implements intended to be operated. A progressive motion is given to the anchor windlasses by means of the prime mover along the sides or ends of the field to be cultivated, and they are thus always kept in a line with the cultivating implement as the work progresses. The windlasses serve alternately to drag the plough or other implement from one side or end of the field to the other. The power of the engine is transmitted and applied to the working of the combined anchor windlasses by means of an endless rope, which first passes round a double grooved sheave on the engine, then round a similar double grooved sheave on each anchor windlass; and this endless rope is guided by bearing pulleys and a capstan which keep it clear of the ground, and impart to it a proper tension. *Patent completed.*

1222. L. MCLACHLAN. *Improvements in governing or regulating light used for taking photographic portraits and other photographic pictures, part of which improvements is also applicable to lighting picture galleries.* Dated April 25, 1862.

This invention consists, firstly, in a method of preventing the direct rays of the sun from falling upon the sitter or other object to be copied, and of modifying or directing the light as occasion may require. This part of the invention the patentee divides into two portions. In the first instance, he causes strips of wood, or other suitable material, to hang downward from the roof, at such a distance apart, and of such a depth as to shut out the direct rays of the sun. These strips, if desired, he hangs upon centres, so that they may be inclined to any angle. Or, in addition to the strips above mentioned, he places cross pieces within the spaces formed by such strips, which cross pieces may also be moved to any angle, so as to govern the light in the other direction. The second division of this part of the invention refers to the side light, in order to govern which he uses projecting slips extending sideways; but in this instance he does not use these by themselves, but in combination with partitions situated within the spaces between them. Another part of the invention relates to a method of preventing light from being reflected from the surface used as a back ground in taking photographic portraits; and, lastly, the invention consists in the application of the above mentioned method of regulating light to the lighting of picture galleries. *Patent completed.*

1223. E. A. L. NEGRETTI and J. W. ZAMBRA. *Improvements in the construction of mercurial minimum thermometers.* Dated April 25, 1862.

This invention consists, firstly, in the employment in minimum thermometers of a platinum plug such as the patentees described in the specification of their patent for "Improvements in the construction of maximum thermometers," dated March, 1852 (No. 14,002). This plug need not, however, be a fixture in any part of the tube, as described in that specification, but may be arranged to act as a kind of valve. Instead of being placed between the mercurial bulb and the indicating tube, as in the improved maximum thermometer above referred to, the plug in the maximum thermometer must be placed behind the bulb, and be so arranged that, when the mercury expands, the latter will either pass the plug, if it be a fixture, into an additional bulb or supplementary reservoir, as described in the specification of a patent dated Oct. 15, 1855 (No. 2306); or the mercury will push the plug forward, if it be adapted, to act as a loose valve; but, on a decrease of temperature, the piece or plug of platinum, if loose, will follow the mercury until it arrives at a contracted part of the bore; or, if the plug be fixed, the mercury will recede from the additional bulb or supplementary reservoir, and also from the connecting tube as far as the plug, and no further, unless force be applied to detach the mercury from the platinum. This part of the invention is based upon the affinity of mercury for platinum, as the platinum plug will allow the mercury behind it to glide past, but will hold on to and retain the column, and prevent it from being detached from the platinum until force be applied. The operation of this instrument will be as follows:—The instrument is set for observation by lowering the indicating tube until the end of the mercury reaches the platinum plug, and is there held by the affinity of the platinum for the mercury. The mercury in the indicating tube will then show the present temperature. Upon a decrease of temperature, the mercury will recede in the indicating tube, and will continue so to do until the minimum temperature is attained. Should any increase of temperature take place in the meantime, the mercury, instead of rising in the indicating tube, will pass or push forward the platinum plug, and will enter the supplementary reservoir; then, should another decrease of temperature take place, say below the minimum heretofore attained, the mercury will first recede in the supplementary reservoir, or bulb, until it reaches the platinum plug, which will hold it there, and thereby indicate the former minimum temperature. The mercury will, from its affinity for the platinum, recede no further therefrom, but will recede only in the indicating tube, and thereby indicate a further decrease of temperature. *Patent completed.*

1224. W. E. NEWTON. *Improvements in chimneys for lamps.* (A communication.) Dated April 25, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1225. D. C. LE SOUEF. *An Improvement in the manufacture of nails, bolts, rivets, screws, eyes, and split-keys or pins.* (A communication.) Dated April 26, 1862.

According to this invention the head of the nail, bolt, rivet, screw eye, split key, or pin, is made of porcelain, or any other kind of earthenware, and when partially dried a hole is partially made in such head to admit the shank or other part of the nail, bolt, rivet, screw eye, or split key or pin, which is further fixed to the head by means of a cement composed of quick lime, white of egg, and slack lime. *Patent abandoned.*

1226. T. E. BROCKLEHURST. *Improvements in machinery for reeling singles, trains, organzines, and sewing silks.* Dated April 26, 1862.

The object of this invention is to obtain an exact number of yards or metres in each skein of silk for dramming and sizing purposes. In performing the invention a rod, with handles running parallel with the reel, and within reach of the workman, is applied to the throwing or winding machine; to this rod is jointed a lever connected to the gearing, by which the reel is driven, by which arrangement, when a thread of silk breaks, the reel is instantly thrown out of gear with the driving power, thereby suddenly stopping the reel, and preventing any more threads being wound on until the broken end is pieced up. *Patent abandoned.*

1227. G. H. LAW. *Improved means for draining flower-pots and other articles or things which require draining in the same or a similar manner.* Dated April 26, 1862.

This invention consists in the use and adoption of a dome shaped, or of a basin-like or hollow conical, or conoidal, or pyramidal, or flat perforated piece of zinc, galvanized iron, tin, or other metal, earthenware, glass, or wood, gutta percha, or other material, provided with openings at the edges or other points thereof, which is to be placed over the hole at the bottom or at other point of the flower-pot or other article to be drained. *Patent abandoned.*

1228. J. G. N. ALLEYNE. *Improvements in machinery and apparatus for the preparation and manufacture of iron and steel.* Dated April 26, 1862.

The patentee claims, firstly, the arrangement of direct-acting steam hammers, wherein one vertical or nearly vertical steam hammer is combined with one or more horizontal or nearly horizontal steam hammers, to act either simultaneously or consecutively upon one and the same piece of metal, substantially as described. Secondly. The arrangement of rolling mills, wherein two or more engines or sets of engines are employed for imparting consecutively two or more different speeds in the same direction to the rolls, one of the said engines or sets of engines being put in gear with the rolling mill when a certain speed is required, and another of the said engines or sets of engines being put in gear with the rolling mill when another speed is required, substantially as described. Thirdly. The arrangement of rolling mills wherein two or more sets of reversing engines are employed, each set of reversing engines running at a different speed, and one set of the said reversing engines being connected to the rolling mill when a certain speed is required, and another set of the said reversing engines being connected to the rolling mill when a different speed is required, the first-named set of engines being then disconnected from the rolling mill, substantially as described. Fourthly. The arrangement of circular saws for trimming the metal after being rolled, wherein the saws and steam engines driving the same are mounted on moveable platforms, the engines being connected to the main steam pipe by a pair or more of trunnion jointed pipes, admitting of the platforms carrying the saws being moved within certain limits without its being requisite to disconnect and reconnect the said jointed pipes from and to the said main steam pipe, substantially as described. *Patent completed.*

1229. E. ALCAN. *An improvement in or addition to carding engines.* (A communication.) Dated April 26, 1862.

This invention consists in adding an endless web to carding engines, as explained with reference to the drawings. *Patent abandoned.*

1230. W. CLARK. *Improvements in collars, wrist bands, and cuffs.* (A communication.) Dated April 26, 1862.

In carrying out this invention, the patentee, firstly, takes strips or brands of cotton, linen, or other fabric, and pastes them on a foundation of strips of paper, or other material, for the purpose of obtaining the thickness and firmness of ordinary stitched collars, and afterwards slightly presses them. Secondly, He obtains a perfect imitation of the stitching, goffering, and other means of ornamenting collars by means of suitable pressure, or a screw or other press. Thirdly, The invention consists in a new method for replacing the button or fastening for securing the collar in its place, and connecting its two ends together as represented in the drawings. *Patent completed.*

1231. S. CHEAVIN and G. CHEAVIN. *Improvements in filtering and purifying water, and in apparatus employed therein.* Dated April 26, 1862.

On the 5th December, 1853, a patent (No. 2820), was granted to one of the present patentees, for "a double action or belt filter," and the construction of this filter was fully described in the specification of the said patent. The filter, as there described, has a bowl or vase at the top; this in practice is found difficult to construct. According to the present invention, the patentees do not employ this bowl, but in place thereof they carry up the body of the filter (which may be cylindrical or of other form) higher than before, and the upper part thereof they employ in place of the bowl, this portion being divided off by a partition, through which passes the small perforated cylinder employed as before to contain sponge or similar material. Around this small cylinder they pack the filtering or purifying material with which the water first comes in contact, and below this there is, as before, another bed of filtering material contained between two perforated plates, and for facility of renewing this material, as well as to facilitate the original construction of the filter, they make the central portion of the exterior vessel (where this filtering bed comes), separate from the upper and lower parts of the same vessel; the parts fit together with flanges, and are secured by screws or bolts. This arrangement allows of ready access to the filtering material. In order to clean the filter from time to time, when it is not necessary to change the filtering materials, they introduce a plunger or piston into the inner perforated cylinder, and work it up and down as a pump. To facilitate this they arrange the exterior vessel so that a lever like a pump handle may be connected with it by a pin or axis, and to this lever the rod of the piston or plunger is also jointed; this method of cleaning is more especially applicable to filters of large size. There is a passage made for the escape of the water employed in cleaning at a point over the filtering beds, as well as below, as is described in the said former specification. In filters or purifiers of large size, several of the inner perforated cylinders may be employed. For the purpose of filtering and purifying water in this and other apparatus, they employ coal, either prepared by washing it with acid, or otherwise. *Patent completed.*

1232. F. G. SPILSBURY, and F. W. EMERSON. *Improvements in the treatment of fusee oil, and for various applications of the same to useful purposes.* Dated April 26, 1862.

These improved processes for treating fusee oil, firstly, in mixing fusee oil with any hydro-carbon, such as petroleum, rock oil, kerosene oil, paraffine oils, turpentole, naptha, or the heavy remaining oils from the distillation of paraffine oils, or of naphtha, or of benzole from coal tar, turpentine, or other similar substances. The proportions vary according to the oils used from 10 per cent. to 100 per cent. of the oils to the fusee oil used. This mixture the inventors submit to distillation, and draw off as much as will come over under a heat of 500 deg. Fahrenheit. Secondly. They dissolve or mix resin, bitumen, coal, paraffine, or napthaline fat, tallow, or oil with fusee oil, and in the same way submit the mixture to distillation, drawing off as much of the oil as will come. Lastly, they pass fusee oil by itself, or any of the aforesaid mixtures, through a red hot tube, which splits the oil into propylic and other alcohols. With certain oils, all or any of these oils so produced, are burned in a paraffine oil or other appropriate lamp; or the inventors use them as solvents for gums and caoutchouc; or such as are without any unpleasant odour they employ as detergents. *Patent abandoned.*

1233. A. BOYLE and T. WARWICK. *New or improved machinery for manufacturing hair pins and cottar pins, a part of which machinery may also be used for cutting off and pointing wires for various purposes.* Dated April 26, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1234. H. W. HART. *Improvements in the manufacture of reflectors and shades for gas and other lights.* Dated April 26, 1862.

This invention relates to reflecting shades for gas and other lights, and consists in the application of a metallic surface to paper or cardboard, the metal forming the reflecting medium or surface, while the paper stuff forms the body of the shade. *Patent completed.*

1235. G. BISCHOF, JUN. *Treating solutions containing copper and silver, or either of them, to obtain metallic copper and silver.* Dated April 26, 1862.

This invention consists in the use of certain processes, by means of which the metals are obtained in the metallic state. For the purpose of obtaining copper from solutions containing this metal, the patentee, in the first place, obtains metallic iron in a finely divided form by reducing the oxide, or sulphuret, or a salt of iron, taking care to avoid fusion. The finely divided iron so obtained he introduces in suitable proportion into the solution containing copper, and in this manner he immediately obtains a precipitate of metallic copper, very much purer than the precipitated copper obtained by means of iron in other forms. *Patent completed.*

1236. G. H. SMITH. *Crinoline or elastic hoops for dresses.* Dated April 26, 1862.

This invention consists in a combination of steel, iron, or other wire with stout threads or cords composed of cotton, flax, or other fibrous substance. Two, three, or more of the wires are arranged longitudinally, at convenient or suitable distances apart, according to the intended width of the fabric to be produced, and between these wire warps are placed, in sufficient number, firm, strong cords of cotton, flax, hemp, or other suitable fibrous substances. All these are arranged in the form of a warp, and are woven into a fabric in the ordinary manner by means of a weft. If desired the wires may be covered with cotton or other fibrous substance, and when the combined fabric is completed it will be sufficiently elastic and much lighter than ordinary crinoline steel hoops. *Patent abandoned.*

1237. A. LESTER. *Manufacture of the fronts or uppers of slippers, shoes, boots, and gaiters, and of mats, bags, &c.* Dated April 26, 1862.

This invention consists in weaving the fabric, of which the intended article is to be made, of a pre-arranged pattern or design, depending upon and suitable to the form or shape of the article intended to be produced. For instance

for the front of the slipper, shoe, or boot, the pattern is to be expressly designed to suit the form of the article intended to be produced, and this pattern, having been drawn upon the ordinary draught paper, is read off, and the chain of cards prepared in the manner usually adopted in preparing looms for jacquard weaving. The fabric is then woven in the piece with the pattern thereon, in such a form that, when it is made up, the article will present the appearance of fine needlework produced by hand. *Patent completed.*

1238. A. V. NEWTON. *Hollow glass ware.* (A communication.) Dated April 26, 1862.

This invention applied to hollow pressed glass ware, also to hollow glass ware produced by blowing, and to glass ware made by a combination of the pressing and blowing processes. The nature of the first part of the invention consists in producing a solid wall to a hollow glass lamp bowl, a tumbler, and to other similar pieces of hollow glass ware, with ornaments formed in or on the glass composing the wall, at a point intermediate of or between the inner and outer plain surfaces of the wall, by a combination of a pressing and a blowing operation or process. The nature of the second part of the invention consists in the combination of the blowing and pressing processes, for the production of glass lamp-pegs and other similar articles, with ornaments on their inner or outer surfaces in a more expeditious and cheap manner than is at present known in the art of glass manufacture. The nature of the third part of the invention consists in a method of producing pressed open work figures, such as flowers, shelves, and leaves, net work, and geometrical figures in coloured glass, and uniting the same to various descriptions of glass ware, so as to stand in bas relief. This manufacture combines the pressing and blowing processes, or repuires but one or the other of them, according to the character of the article being made, or as the fancy of the operator may dictate. *Patent completed.*

1239. A. V. NEWTON. *Lamps for burning coal, oil, and other hydro-carbons.* (A communioation.) Dated April 26, 1862.

The metal wick tube of the burner of these lamps is surrounded by a tube of earthy cement, porcelain, pipe, and other clays, artificial or natural stone, pottery, earthenware, opaque glass, or other analogous materials which are good non-conductors of heat, and also using in connection therewith a cone or deflector, constructed either of the material above-named, or of metal enamelled and attached to the tube surrounding the wick tube, in such a manner as to isolate the cone from the external tube. By this means only a suitable proportion of the heat evolved by the flame is conducted down to the lamp, and the flame is consequently not supplied with an excess of vapour, but is provided with a supply of oxygen amply proportionate to the vapour without a draught chimney. *Patent abandoned.*

PROVISIONAL PROTECTIONS.

Dated July 7, 1862.

1958. J. McGeary, Bayham-terrace. Improvements in the manufacture of gas, and the apparatus to be employed for that purpose. (Partly a communication.)

Dated August 23, 1862.

2355. F. T. Moison, chemist, 13, Rue Gaillon, Paris. Improvements in the process of cleaning organic matter.

Dated August 30, 1862.

2409. W. E. Gedge, 11, Wellington-street, Strand. Improvements in machinery or apparatus for manufacturing velvet. (A communication.)

Dated September 26, 1862.

2629. W. E. Gedge, 11, Wellington-street, Strand. Improvements in the construction of leaden window sashes, casements, or glazed coverings or partitions. (A communication.)

Dated October 9, 1862.

2725. J. H. Johnson, 47, Lincoln's-inn-fields, gentleman. Improvements in polishing precious and other hard stones, and in the machinery or apparatus employed therein. (A communication.)

Dated October 13, 1862.

2757. W. G. Haig, Canonbury Park North, gentleman. A new article of apparel to be worn instead of, or in addition to, a shirt front and waistcoat.

Dated October 14, 1862.

2766. J. Snider, jun., 51, Dorset-street. Improvements in the construction of "Hansom cabs," and other similar vehicles.

Dated October 27, 1862.

2888. W. J. Williams, 51, Dorset-street, Salisbury-square. Improvements in the construction of field rakes for agricultural purposes. (Partly a communication.)

Dated October 28, 1862.

2902. G. H. Smith, North Perrott, Somerset, twine and web manufacturer. Improvements in the manufacture of crinoline or elastic hoops for dresses.

Dated October 29, 1862.

2910. A. Krupp, Essen, Prussia, cast steel manufacturer. Certain improvements in breech loading ordnance and fire-arms.

Dated October 30, 1862.

2928. G. Mayall, jun., Liverpool, broker, and J. Hollingworth, Micklehurst, Chester, manager. Certain improvements in machinery or apparatus for preparing cotton and other fibrous materials for spinning.

2930. G. Piggott, Birmingham, manufacturer. New or improved machinery for punching, shearing, and rivetting sheets or plates of iron and other metals and alloys.

2932. J. Horton, Etna Works, Smethwick, near Birmingham, Stafford. Improvements in the construction of armour plated ships and fortifications.

2934. A. Guild, Horbury-gardens, Notting-hill, merchant. Improved apparatus for preparing and treating the leaves and stalks of fibre-yielding plants, and for cleaning and dressing the same.

Dated October 31, 1862.

2936. W. Astrop, Jubilee-street, Stepney, stationer. Improvements in the manufacture of paper.

2940. D. Spink, esquire, Spaxton, near Bridgewater, Somerset. Improvements in the method of propelling ships and other vessels.

2942. C. Gubbins, esquire, York-place, Portman-square. Improvements in irons for ironing.

2944. H. Thomson, Buckden, Huntingdon, engineer. Improvements in railway signals.

2946. G. Speight, 5, St. John-street-road, Clerkenwell, manufacturer. An improvement in the manufacture of collars for men's wear.

2952. W. Jenkins, Troedy Rhiw, Merthyr Tydvil, Glamorgan, viewer. An improved mode of and apparatus for cutting coal.

Dated November 1, 1862.

2958. E. Stevens, 15, Hunter-street, Brunswick-square. Improvements in iron shelves, stands, and racks.

2960. E. Hopkins, Clarendon-gardens, Maida-hill, civil engineer. An improved mode of and apparatus for treating ores for the extraction of metals therefrom.

Dated November 3, 1862.

2964. C. Shield, Newcastle-upon-Tyne, engineer. Improvements in the manufacture of malleable cast iron.

2968. E. Humphrys, Deptford. Improvements in the construction of centrifugal pumps.

2970. T. O. Clark, Clapham-common, upholsterer. An improved portable spring bottom bedstead. (A communication).

2974. W. H. Stallard, Mark-lane, merchant. Improvements in umbrellas and parasols.

Dated November 4, 1862.

2978. J. McKean, Walmer-bridge Mills, near Preston, manufacturer, and T. Greenhall, Manchester, flour factor. Improvements in sizing or dressing yarns or textile materials.

2980. T. Logan, Kensington, gentleman. An improved kaleidoscope.

2986. J. E. F. Lüdeke, Marke, Hanover. Improvements in magneto-electric apparatus for obtaining and applying motive power.

2988. A. Wall, Canton-street, East India-road, Poplar. Improved processes for purifying lead, and extracting and separating silver therefrom, and in machinery for those purposes.

Dated November 5, 1862.

2990. S. Robotham, Birmingham, wire weaver. Improvements in carriage bodies.

2992. W. Johnson, 166, Buchanan-street, Glasgow, civil engineer. Improvements in the arrangement and construction of pillars or standards for supporting telegraph wires. (A communication.)

2994. R. A. Brooman, 166, Fleet-street, patent agent. Improvements in taps or cocks. (A communication.)

2996. C. Shield, Newcastle-upon-Tyne, engineer. Improvements in the manufacture of malleable cast-iron.

2998. J. Petrie, jun., Rochdale, ironmonger, and J. Teal, Sowerby, York, mechanic. Improvements in machinery or apparatus for washing wool and other fibrous materials.

3000. D. Hill, 3, Camden-road, Holloway. Improvements in apparatus for stamping or marking and counting bank notes and other documents.

3002. T. Brown, 85, Wood-street, Cheapside. Improvements in machinery for surfacing fibrous materials. (A communication.)

Dated November 6, 1862.

3004. W. E. Gedge, 11, Wellington-street, Strand. An improved lift and force pump. (A communication.)

3006. H. Griffin, Silvertown, Essex, engineer. An improved method of securing india-rubber cylinders or rollers and blocks upon spindles and other bodies on which they are to be mounted.

3008. J. A. Fullarton, Manchester, iron merchant. Improvements in machinery or apparatus for painting or coating hoop iron and other strips, bars, rods, or other such articles of metal, wood, or other material.

NOTICES OF INTENTION TO PROCEED WITH PATENTS.

1942. T. O. Dixon. Heating or warming rooms or buildings.

1957. T. Edwards. Indices for gas, water, and other fluid meters.

1958. J. McGeary. Manufacture of gas. (Partly a communication.)

1962. C. B. Gruner. Photographic apparatus.

1966. J. Rigby. Breech-loading guns.

1969. H. Wethered. Construction of handles, latches, or fastenings for doors, gates, and windows.

1973. A. Gilbey. Washing and cleansing bottles.

1974. H. S. Pontifex. Distributing water applicable to cleansing casks or other vessels, or for other purposes.

1977. H. Eschwege. Purifying wood and other vinegar.

1986. J. Mander. Crochet needles and crotchet needle holders.

1991. J. Leeming. Jacquard or index machines.

1994. J. H. Johnson. Braiding machines. (A communication.)

2000. J. Miller. Steering ships and other vessels.

2014. Hon. W. E. Cochrane. Railway fastenings.

2016. G. Lowry. Machinery for carding and cleaning fibrous materials.

2023. P. A. L. Canonicat. Filtering water.

2024. G. Faweus. Building boats.

2026. O. P. Drake. Vaporizing and aerating a liquid hydrocarbon.

2027. R. Ridley, and J. G. Jones. Ventilating mines and other places.

2028. A. Leslie. Applying steam or other motive power to cultivate the soil and to actuate wheeled carriages.

2035. T. G. Ghislin. Treatment or preparation of British and foreign algæ, and the application of the same to various branches of the arts and manufactures.

2048. T. B. Daft. Manufacture of mats.

2049. T. B. Daft. Manufacture of vulcanized india-rubber thread.

2061. R. A. Brooman. Revivifying animal black. (A communication.)

2064. W. E. Newton. Ordnance. (A communication.)

2096. A. Vignon. Apparatus for extinguishing fires. (Partly a communication.)

2108. W. Clark. Manufacture of fishing and other nets. (A communication.)

2165. W. Clark. Gas burners. (A communication.)

2168. J. W. Dixon, jun. Coffee urns.

2169. J. W. Woodford. Raising or forcing water.

2209. M. A. F. Mennons. Self-inking hand stamp. (A communicarion.)

2249. A. J. Martin, J. Gooss, and J. Bush. Apparatus for distillation.

2261. A. B. Childs. Machinery for cutting veneers. (A communication.)

2386. E. Astel. Urinary utensils.

2612. M. A. F. Mennons. Chair settees. (A communication.)

2785. F. F. Prud'homme. Raising water.

2823. W. A. Turner, and T. T. Coughin. Measuring fabrics.

2898. E. Hooper. Roofing tiles.

The full titles of the patents in the above list can be ascertained by referring back to their numbers in the list of provisional protections previously published.

Opposition can be entered to the granting of a patent to any of the parties in the above list who have given notice of their intention to proceed, within twenty-one days from the date of the *Gazette* in which the notice appears, by leaving at the Commissioners'

NOTE.—Specifications will be forwarded by post from the Great Seal Patent Office (publishing department) on receipt of the amount of price and postage. Sums exceeding 5s. must be remitted by Post Office Order, made payable at the Post Office, High Holborn, to Mr. Bennet Woodcroft, Great Seal Patent Office.

THE
MECHANICS' MAGAZINE.

LONDON, FRIDAY, NOVEMBER 28, 1862.

THE PROGRESS OF THE MODERN MANUFACTURING SYSTEM.

THE above is the main title of a remarkable paper lately published by the well known political economist of France, M. Michel Chevalier. It forms the introduction to the general report on the International Exhibition of 1862, compiled from the 99 special reports of the 130 French jurors. This special commission, chosen by the Emperor himself, has worked under the presidency of Prince Napoleon. International Exhibitions promise to become an international institution, enabling the nations to "take stock" of each other's progress. The remarkable man at present at the head of France seems to have spared no means of enabling his people to read aright the great lessons offered at the late World's show. These French reports promise to be its only systematic record.

It may not be uninteresting to notice what a chosen body of French *savants* and manufacturers, our rivals and opponents in so many things, have thought about our Exhibition. We may with justice call it ours, for although nominally an international affair, still the greater part of the things present were more or less English. The eastern annex, for instance, was an entirely English exhibition, and France and Germany made, from various reasons, but a comparatively small appearance in the western annex. We allude more particularly to these two parts of the Exhibition, as they fall more specially within the province of the MECHANICS' MAGAZINE.

The tone of the whole essay is very cordial towards England, and it also expresses much satisfaction at the results of the Exhibition. There are some eloquent pages about the civilizing influence of the engineer, and of the science of mechanics. Volumes might, no doubt, be written on this subject.

M. Chevalier considers the following great truth is to be evolved from a consideration of the great Exhibitions of 1851, 1855, and 1862, namely, that the producing powers of mankind are continually on the increase, and that this increase is only of comparatively recent origin. What he understands by producing or manufacturing power is the work that one man can do in any given time. For instance, supposing that a rolling mill, with 100 workmen, delivers 10,000 tons of iron in a year, the manufacturing power of each man will be 100 tons per annum. He gives the following interesting instances of this progressive progress of manufacturing power:—Twelve years ago the Californian miners used to get at the gold by simply washing the alluvial soil in tin pans. This plan is the same used by the ancient Egyptians, as still shown on their old monuments. Many people will have seen a man in a red shirt, washing gold in the Exhibition, upon this plan. These Californian deposits of gold, in course of time, got to be very poor, and would no longer pay hand labour. By using machinery, however, the Californian miners can work a digging with considerable profit, even when the soil contains only 1 lb. of gold to 4,000,000 lbs. of alluvium. The price of a day's labour in California is 20f., and the expense of washing by hand labour a cubic metre of earth is 75f. This expense has been] reduced to 3 centimes a cubic metre. This represents, therefore, a manufacturing progression of 1 to 2,500.

In the manufacture of iron, M. Chevalier considers that this productive power has increased thirty times, dating 600 years back. Dating from the year 1769, when Arkwright took out his first patent, one man can now spin 400 times more thread than the best spinner of that period. The year 1769 is certainly an extraordinary one in history. Napoleon the First, Wellington, Mehemet Ali, Castlereagh, Humboldt, Cuvier, and M. T. Brunel, were all born in the same year that saw the beginning of cotton spinning. The present method of grinding flour, compared with the clumsy and painful method of ancient times, shows a gain in the productive power of one man of about 150 times. In the manufacture of lace, one workwoman can now do the work of one hundred without the machine.

In the manufacture of sugar the small crystals mixed with syrup are now placed in a centrifugal machine making about 1,400 revolutions per minute. The liquid is driven off by the centrifugal force, while the sugar remains, and it only requires to be dried in a stove. The whole operation of refining now lasts only as many days as it formerly used to last months. Looking-glasses were formerly made by using an amalgam of mercury and tin. Silver, as first proposed by Liebig, is now used instead of the mercury. The process of fixing the amalgam used to last six weeks for a large glass. The present process lasts only 40 minutes; the silver adheres much better than the tin amalgam, and, above all, the manufacture is not unwholesome for the workmen. Unfortunately, this increase of manufacturing power is not confined to peaceful purposes. An iron-plated ship has engines of, say, 1,400 nominal horse power. The real horse power of this is about five times the nominal, namely 7,000-horse. As a steam horse power is twice as much as a flesh and blood horse power, and as the engine can work 24 hours, while the cart-horse can only work 8 hours, a steam horse power can, therefore, do as much as 6 common horses. This steam apparatus is, therefore, as much as 42,000 flesh and blood horses. With the exception of the horses belonging to the great army Napoleon the First led to Moscow, there probably never has been such a number of flesh and blood horses together.

In alluding more especially to advances made since 1851, M. Chevalier states that, in 1848, there were only 1,821 kilometres of line of railway in France. There are 10,500 kilometres at present, and an almost equal length in course of construction. Forty years ago, in Paris, a 50-horse beam engine cost, complete, with boiler, &c., rather more than 100,000f. A horizontal engine of the same power costs now rather less than 50,000f. The demand for portable engines (locomobiles) has everywhere largely increased, particularly in France, since 1855. M. Chevalier gives the honour of the invention of the steam hammer to M. Bourdon, formerly of Creuzot. The belief that M. Bourdon is the inventor of this tool seems to be general on the Continent. It is a pity that the stupidity of the then partners of Mr. Nasmyth allowed the honour of making the first steam hammer to be wrested from our country. It is curious to observe how each nationality puts forth its own special claims to almost every great invention. There is a separate inventor of the screw propeller for England, France, and Germany. Germany and Holland both claim the invention of printing. England and Germany both claim the discovery of gunpowder. France claims even the steam engine for Solomon de Caus and Denis Papeir. We might give many more instances of this. Somehow or other, however, we English have first practically applied all these things. It was at Crecy that cannon was first used. We first had a free press, and the first real steam engine in France was imported from England.

M. Chevalier recalls that, in 1851, Krupp sent a small cast-steel cannon to the then Exhibition. At the Paris Exhibition of 1855, he had an ingot of steel of 5½ tons. He has greatly surpassed these by his 1862 exhibit, his large cranked axle of cast-steel weighing no less than 20 tons. We ourselves have no doubt that, sooner or later, every detail of an engine will be made of steel. In alluding to the Bessemer process, M. Chevalier remarks that it is a discovery of greater importance than all the gold mines of California and Australia.

He also lays great stress on the fact of our Great Northern Railway, replacing the worn-out iron rails by similar ones of steel, with the expectation that these latter will last three times as long. There are some interesting observations about aluminium. It is stated that when M. Sainte-Claire Deville first made it, its price was 3,000f. the kilogramme. It now costs only 80f., and it would be even less if a large demand should take place. As is well known, a common brick is mainly composed of alumina, the oxyde of this metal. According to M. Chevalier, a very strong piece of ordnance has been made in France of aluminium bronze. It has also been employed for the bearings of shafts, with very good results. Without professing to have an intimate practical acquaintance with this substance, we do not believe that it will ever take rank as a very valuable metal. It is very light, and the power of any metal to resist decomposition while in contact with oxygen is generally in a direct ratio to its density. As an alloy with other metals it may prove very valuable. It appears that the French jurors have been very much struck by the progress, since 1851, in artistic taste of the English art manufactures. This has been especially the case as regards the design and colouring of woven materials, and the shapes of furniture work. This is consolatory to those English people who think we have not advanced in this direction. Good artistic taste is more particularly the forte of the French manufactures in general. It is curious that the shapes of their machinery at Kensington showed such a great want of symmetry.

It would appear that our laws, or rather the absence of laws, bearing upon manufactures, have been investigated by the order of the Emperor with a view to reform similar French legislative enactments. In France permission must be asked of the Government to build a blast furnace, or even a refining furnace. Complaint is also made by M. Chevalier that the laws about steam-boilers are oppressive and absurd. They prescribe such a testing pressure that the boiler is thereby injured, and such a great thickness of plate that it is impossible to use steel or plate of the best kind. This is a useful lesson to those well-meaning people who wish to trammel the English boiler-makers. What is required in England is simply the extension to all parts of the useful boiler insurance societies, which first arose some six or seven years ago in Manchester.

As is well known, the whole net of French railways has been traced out by the Government. It is, no doubt, very well arranged; but, from there being no competition, the companies work the trains at a very slow speed. A Manchester manufacturer, on sending off his bales in the evening, can deliver

them to the buyer in London the next morning at 10 or 11 a.m. M. Chevalier states that, under the present French railway management, this would take seven days. He mentions that he has known several cases in which goods have regularly taken one whole month to be conveyed from the north to the south of France. In England, competition induces high speed, but the lines do not pay, and accidents seem to be more frequent. Both these opposite systems seem to cause dissatisfaction. The French Government, having laid out and guaranteed the railway lines, is now called upon to regulate the speeds of the trains. Once a Government begins to interfere in matters of this kind, it is for ever after bound to keep up this superintendence. Any spontaneous action is thus rendered impossible.

A reform of the patent laws seems to be as much wanted in France as with us. M. Chevalier seems to take the same view about patents as the *Times* and Sir William Armstrong. Let us hope that the new patent law to be carried next session will enlighten him on this subject. The agitation against the patent law seems to be raised by the large French manufacturers in the same way as with us. No doubt they understand as well as their English brethren that, without the protection of a good patent law, there will be no invention or alteration, and therefore less depreciation of old patterns already in stock. At the same time, the French manufacturers have to undergo peculiar hardships in some cases. The neighbouring countries of Prussia and Switzerland do not recognise any patent law. A new article can thus be manufactured in these countries without any royalty having to be paid. The result is that the maker, obliged to pay a royalty—is driven out of many markets.

The same thing happens with us. As soon as the Prussian makers hear, for instance, of any new agricultural implement, they come over and buy the machine. They then copy it, and are able to make it, free of royalty, for the whole North of Germany. Such a state of things is a disgrace, and the system is simply an organised robbery. It does great harm to Prussia itself. Instead of designing, the manufacturers of that country merely copy. They are less advanced in many manufactures than they otherwise would be. Patentees are teachers and reformers of manufacturing industry. They are frequently the missionaries of science, and they form a continual propaganda of industrial progress.

In this short notice we have given but a faint idea of this very interesting and suggestive essay. M. Michel Chevalier remarks at the conclusion that this great meeting of the industry of all nations has been for all mankind what the Olympic games were to the Greeks. It has been a meeting of the great family of nations where, at least for a short time, national hatreds and prejudices have been laid on one side. Let us hope, therefore, that the ordnance exhibits will be articles the least in demand.

TT.

STEAM FIRE-ENGINES.

Steam fire-engines, like almost everything else good in this country, have had to fight an uphill battle. Thirty years ago Mr. Braithwaite demonstrated their utility, and, we may say, their superiority; but so many objections were raised against them, that that gentleman was induced, after years of effort, to abandon the struggle in favour of their adoption. Had he been encouraged instead of being discouraged, the probability is that the metropolis would have been better able to subdue great fires than it is at the present moment. Whilst, however, objections were urged, and official authority exerted, to prevent the use of steam fire-engines amongst ourselves, the Americans were on the alert to improve on the engine patented and produced by Mr. Braithwaite. Steam fire-engines have accordingly been extensively used for years past in New York, Philadelphia, and other American cities. The successful employment of these engines in America, and the absolute necessity for something more powerful than our ordinary fire-engines, to cope with occasional gigantic metropolitan conflagrations, have broken through prejudices, stimulated inventors and manufacturers, and steam fire-engines are in demand. Why should they not? Certainly if they are good for American cities they are equally good for London. When a fire breaks out the sooner it is quenched the better. And as steamers can be moved as rapidly, managed as easily, and be made to throw four or five times as much water as land engines, the sooner they are adopted in the metropolis the better. They can, no doubt, be worked cheaper. A half-a-hundred of coals will do more service than forty men. Besides, if steamers were more generally used, there would be fewer inducements for incendiary acts. It would be better if all rewards in connection with the discovery of fires, and for the first engine which gets at the fire, were immediately and for ever abolished. The policeman who first discovers a fire has, we believe, a reward of £2, and the engine which first gets at a fire has £5. Our criminal records too abundantly testify that men will occasionally commit crime with the expectation of getting small rewards. Not long since a police-officer, in one of the metropolitan divisions which we could name, was the first to discover no less than three fires in a very short space of time. This created suspicion, and means were used to discover the causes of the fires. The police-officer no sooner heard of the inquiries which were set on foot, than he fled. Other facts, equally full of suspicion, have, from time to time, come to our knowledge. Some years since, in one of the eastern counties, a man who had discovered no less than 11 burning ricks was arrested on suspicion. He afterwards confessed that he set fire to the ricks for the purpose of getting the paltry reward, in each case, of 1s. for being the first to give an alarm of the fire. We hope, therefore, that the proper authorities will, before long, see the propriety of abolishing all rewards.

On Monday last there was a competition trial of steam fire-engines at Messrs. Hodges's Distillery, Lambeth. Messrs. Shand and Mason and Mr. Roberts, of Millwall, did not on this occasion compete. The first fire-engine tried was the one recently manufactured by Messrs. Merryweather, and which was described and illustrated in the Mechanics' Magazine, May 2, 1862. The working of this engine excited some amount of curiosity on account of its working without a fly-wheel, thus securing a uniform speed of piston. The other steam fire-engine tried was manufactured by Messrs. Easton and Amos, on Mr. Wellington Lee's American patent, which also works without a fly-wheel. The advantage of this engine over others is said to consist in its arrangement as a duplex engine, with two double-acting pumps, the piston-rod of one cylinder creating a lever, which turns the steam on to the second cylinder.

The following are the results of the trials of the two steamers:—

Merryweather's steam fire-engine "Deluge" lighted fire at two o'clock.

	min.	sec.	
In	7	30	steam gauge moved.
,,	8	30	steam gauge showed 10 lbs.
,,	8	50	... ... 15 lbs.
,,	0	30	... ... 20 lbs.
,,	9	50	... ... 50 lbs.

At this point the engine started.

Lee's steam fire-engine, E size, lighted fire at 3 h. $22\frac{1}{2}$ min.

	min.	sec.	
In	6	15	steam gauge moved.
,,	7	30	steam gauge showed 10 lbs.
,,	8	0	... ... 20 lbs.
,,	9	0	the engine started.
,,	10	15	steam gauge showed 30 lbs.
,,	10	55	... ... 40 lbs.
,,	11	30	... ... 50 lbs.

The size jets used by Merryweather's engine were $1\frac{1}{4}$ in., $1\frac{3}{8}$ in., and $1\frac{1}{2}$ in. respectively. Those used by Lee's engine were $1\frac{1}{4}$ in., $1\frac{1}{2}$ in., and $1\frac{3}{8}$ in. diameter.

Although the state of the wind was very unfavourable to lofty throwing, both engines were played against a chimney 140 ft. high, and both threw a jet of water about 160 ft. high; and, as a final trial, each was connected to a long length of leather hose led to the top of the fire observatory, 135 ft. in height. A branch and nozzle being attached to the end, and a jet played both horizontally and vertically with good effect. In this experiment Lee's engine, after running for some time, raised the pressure in the air vessel to an extent sufficient to burst the conducting hose about half way up the mast.

As regards the mode of raising steam, two different plans were pursued. In Merryweather's engine a jet of steam was thrown into the chimney as soon as there was sufficient pressure to do so, for the purpose of creating a draft through the fire. In Lee's, there was no artificial jet of this kind, but as soon as possible the engine was started, and by this means a blast in the chimney created.

While under trial, Lee's engine was worked without a spark-catcher, although there is the means of attaching one when required. In the absence of this spark-catcher, burning cinders were sent from the funnel at a considerable height, and in great profusion. In throwing to great altitudes, the power required increases in a very much higher ratio than the height attained by the jet; hence this increase of power can only be attained by an increased production of steam, and a powerful blast becomes requisite.

In locomotive engines, where the same conditions apply in the case of high speeds, spark-catchers, variable blast nozzles, and other contrivances, have been adopted, and it is probable that in heavy work similar appliances would have to be adopted in the case of steam fire-engines.

The experiments gave great satisfaction to a very large number of visitors. Merryweather's was the first fire-engine manufactured by that firm, and it did its purposed work very ably. The latest experiment of the day was with a second and smaller steam-engine, built by Mr. Merryweather, which when completed will weigh only 30 cwt., and can be drawn with ease by one horse or three or four men. The object in this case was to discover in how short a time steam could be got up, and the result proved that in eight minutes 37 lb to the square inch was generated, and 100 lb. in $9\frac{1}{4}$ minutes. This is said to be the fastest generator of steam on record.

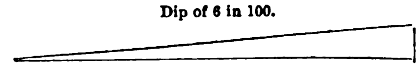
The committee of the proposed Moffatt Railway have given the Parliamentary notices, and Mr. Miller, the engineer, has been over the line with his assistants completing the plans for deposit in the end of this month.

THE ATLANTIC TELEGRAPH.

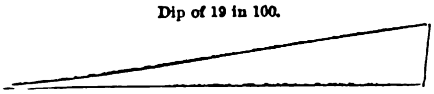
The following communication has been forwarded to the Atlantic Telegraph Company by Mr. Hoskyn, R.N., the gentleman who has recently surveyed portions of the western coast of Ireland for the company, by order of the Lords of the Admiralty, with a view to improve the line along which the intended cable to Newfoundland is to be taken:—

"Dear Sir,—With reference to the conversation I had with you recently in Dublin on the subjects connected with my Deep Sea Sounding cruise in the 'Porcupine,' I think that there can be no reasonable doubt now but that the descent from the Irish bank to the bed of the ocean is all that we can desire for he safe laying of the cable. So far from its being a precipice, a locomotive might run up some of the inclines, and many turnpike roads have steeper ascents, as the following diagrams more clearly illustrate, a dip of 6 ft. in 100 being the least, and 19 ft. in 100 the greatest we met with:—

Dip of 6 in 100.



Dip of 19 in 100.



"The face of this slope—and indeed the bed of the ocean everywhere when below the depth of 500 or 600 fathoms—is covered with the soft clayey substance called by seamen 'ouze.' This deposit, in the opinion of Professor King and other naturalists, is going on so copiously and unceasingly, that a cable once laid would, in the course of a few years, be 'covered up,' and so for ever sealed against the action of all external agencies.

"The question, then, is, what kind of cable will be best adapted to these conditions of the bed of the ocean, and, at the same time, the cheapest and easiest laid across the Atlantic from Ireland to Newfoundland. And here I am sure that all seamen and practical men will agree with me that the lighter it is the better, so that it has but specific gravity enough to sink it. Much stress was formerly laid on the strain it would be subjected to from counter-currents, but our larger experience has taught us that these, like the precipice, are imaginary dangers, and that, in the part of the ocean the cable will cross, there are even no surface currents that will injuriously affect it—these appearing to be more of a surface drift, whose direction and strength depends on the prevailing wind.

"That the cable should hold together during its descent through the still waters of the ocean does not require any great strength, probably the copper core alone would give it sufficient; but if, as we are told, a cable with a core of 5 cwt. of copper to the mile, coated with gutta percha, will have a breaking strain of 7 cwt., it surely is all that is necessary for its safe descent to the bottom.

"A cod line, with a 90 lb. weight attached for a sinker, occupies about 42 minutes in descending to a depth of 2,000 fathoms; and with a line of this description, made by Messrs. Newall, we have recovered a 64 lb. sinker from a depth of 1,750 ft.; this will probably give some idea of the opposing force the cable will meet in its descent to the bottom.

"If not required for strength, of what use, then, is the iron wire? It will not prevent the attacks of minute animals, for in laying out it is always more or less strained and opened, and moreover these have never been found to attack gutta percha. Supposing the bottom of the ocean to be free from volcanic action, as it certainly appears to be between Ireland and Newfoundland, I know of no other force that would be likely to injure the cable. Careful soundings at intervals of 5 or 6 miles would teach us if any such danger existed, and how to avoid it. I think, therefore, that the lightest cable that can be made would be the one most likely to solve this problem successfully. The shore ends, and where it crosses shoal water must, of course, be protected. The comparatively small cost of such a cable, and the ease with which it may be run out, makes it worth a trial; if one should succeed, of which I have no doubt, we might soon have duplicates and triplicates.

I remain, &c.,
R. Hoskyn, Master R.N.,
Late Commanding "Porcupine."

"Holywood, Belfast, Nov. 12, 1862."

The following letter has also been addressed to the Atlantic Telegraph Company respecting a future cable:—

"My Dear Sir,—Referring to our conversation this morning upon telegraph cables, I subjoin a few facts that will doubtless interest you.

"The manufacture of gutta percha since 1857 has been greatly improved, and its insulating power increased thereby more than ten times.

"The Dunwich Zandvoort cable, made in 1858, and 134 statute miles in length, contains four conducting wires of 110 lb. to the statute mile; two of them are insulated with two coatings of gutta percha only. The other two are insulated also with two coatings of gutta percha, but between the wire and the first coat of gutta percha, and between the two layers of that material, there is a film of Chatterton's compound (a mixture of vegetable tars and gutta percha).

"The Lowestoft and Zandvoort cable, made in 1862, contains four conducting wires of similar dimensions to those in the Dunwich cable, but each wire is insulated with three coats of gutta percha, and between each of those coats there is a film of Chatterton's compound.

The wires tested in August last in the following ratio (nearly):—

1858 cable.	2 wires plain gutta percha alone...	1
	2 wires „ with compound	1½
1862 cable.	All four	11

"The insulation having improved in the ratio of 1 to 11.

"The 1858 (Dunwich Zandvoort) cable improved in insulating power considerably after submersion a few months, and although submerged four years, its insulation is now as high as it ever was.

"The conducting power of copper has likewise been considerably improved.

"The conducting power of the 1862 cable is 25 per cent. greater than the 1858 cable; this improved conducting power increases the speed of the cable in a corresponding ratio.

"The appliances for testing cables during manufacture and otherwise have very considerably advanced; and minute leakages, that in 1858 would have escaped notice, are now easily detected.

"The speed of a cable is dependent upon the conducting power of the copper, its dimensions, and upon the insulating material.

"The speed of a cable of any length can be indefinately increased by augmenting the dimensions of the conductor and of the insulating material.

"The cost of working a cable accross the Atlantic with a large core, whose speed is 12 words per minute, will be no greater than that of working a smaller core of only 1 or 2 words per minute.

"The larger core giving 12 words per minute, will cost but little more for the external covering and submersion than the smaller core giving but 1 or 2 words per minute. £350,000 will make and lay a cable across the Atlantic, with a conductor weighing 93lbs. to the mile. £700,000 will make and lay a cable with a conductor of 560lbs. to the mile. Hence there would be a manifest economy in using a cable whose speed of transmission is pretty rapid.

"To go beyond the speed of 12 words a minute, would not be attended with a corresponding economy, because the operators cannot work with so much efficiency at higher speeds.

"The Atlantic Telegraph Company would have but two stations, in a distance of nearly 2,000 miles, and could, consequently, afford to pay such a price as would secure the services of the most skilled operators to be found, together with the most improved instrument which science can produce. Two very important items in the commercial success of the undertaking.

"I am, &c.,
C. F. Varley,
"Electrician to the Electric and International Telegraph Company, and to the Atlantic Telegraph Company."

THE MANCHESTER ASSOCIATION FOR THE PREVENTION OF STEAM BOILER EXPLOSIONS.

Chief Engineer's Monthly Report.

At the last ordinary monthly meeting of the executive committee of this association, held at the offices, 41, Corporation-street, Manchester, on Tuesday, Nov. 25, 1862, William Fairbairn, Esq., C.E., F.R.S., in the chair, Mr. L. E. Fletcher, chief engineer, presented his monthly report, of which the following is an abstract:—

"During the past month there have been examined 365 engines and 547 boilers. Of the latter 8 have been examined internally, 60 thoroughly, and 479 externally, in which the following defects have been found:—Fracture, 5 (1 dangerous); corrosion, 38 (3 dangerous); safety-valves out of order, 13; water gauges ditto, 31; pressure gauges ditto, 9; feed apparatus ditto, 6; blow-off cocks ditto, 47 (1 dangerous); fusible plugs ditto, 3; furnaces out of shape, 6 (2 dangerous); blistered plates, 3; deficiency of water, 1. Total, 162 (7 dangerous). Boilers without glass water-gauges, 10; without pressure gauges, 2; without blow-off cocks, 38; without back pressure valves, 78.

"An explosion has occurred this month to the boiler of a first-class passenger locomotive engine, by which 3 persons were killed and others injured. It was considered to be perfectly safe, had been on duty the previous day, and was being cleaned ready for work at the moment the explosion occurred.

"It will be remembered that reference was made in the July, 1861, report, to another explosion of a locomotive boiler, which took place while the train was running; and since that time three others have occurred in addition to the one first alluded to, thus making five during that period with this class of boiler.

"The cause of explosion in four of these cases proved to be thinning of the plates from internal corrosion. I have only had an opportunity of examining the plates of one of these exploded boilers, but from official reports, it appears that the corrosive action had developed itself in a very similar manner in each instance, which in the one personally examined was as follows:—The corrosion had eaten grooves or furrows parallel with and close to the edge of the overlaps of the plates, at some of the longitudinal seams of rivets; the furrows being on the outer plates of the overlap, while the deepest one, and that from which the explosion had sprung, was

situated nearly midway between the smoke-box and fire-box.

"This furrowing action will be at once recognized by those who have been in the habit of observing the influence of wear upon the ordinary internally fired double-flued boiler, in general use in Lancashire. In this boiler the furrow is found on the inner surface, both of the front and back end-plates, but more especially at the front, and lies close to the edge of the internal flue angle-iron, which it partially encircles; the furrow being deepest at the crown, and gradually dying out in about six or nine inches on each side. It is sometimes found in the root of the angle-iron itself; the choice of position between the plate and angle-iron, apparently depending upon their comparative power of resistance. When the plate of the furnace-tube is flanged, the furrow more frequently occurs at the springing of the flange than at the end-plate. Furrowing also is very commonly found at the transverse seams of rivets at the underside of boilers; the furrows in these cases being immediately at the edges of the overlaps, and most frequently on the external surface of the plates, but sometimes on the internal. This action is more severe in long boilers than in short ones, and at the middle of their length rather than at their ends. It is seldom, if ever, developed at the longitudinal seams of these boilers, except where leakage takes place, and is then found to be most severe when the objectionable plan of construction is adopted, of placing the seams of rivets in one continuous line from one end of the boiler to the other. Such are some of the manifestations of furrowing constantly met with in the boilers under the inspection of this association, and it may be interesting to attempt to trace the cause.

"Furrowing appears to be the result of corrosive and mechanical action combined. The mechanical action, such as an alternate buckling of the plates, strains and frets them, and thus renders them more susceptible to the influence of corrosion than the parts at rest. Where these furrows are internal, the corrosive element is furnished by the water, which is rarely, if ever, free from acidity; and when the furrows are found externally in the flues, as explained above, the corrosion may perhaps be attributed to the influence of gases.

"The cause of the buckling action varies according to the position in which it occurs.

"In the stationary boilers above referred to, when found in the front end plate, it may be ascribed to the alternate elongation of the internal flues, more especially at the furnace end; and, when at the bottom of the external shell, to the unequal expansion of the plates consequent upon the different strata of temperature in the water. The temperature of these strata varies with the distance from the bottom of the boiler, in proof of which it may be stated that it is frequently found that while the water is boiling on the surface, that at the bottom of the boiler will not scald the hand. Those boilers are most conducive to this inequality of temperature which have a defective circulation of water, are so set that the last heat from the fires passes beneath them, and fed with comparative cold water introduced at the bottom. It will be readily seen how these varying temperatures induce unequal expansion of the plates, and thus put upon the seams of rivets most irregular and severe strains. In this way, it is thought that the buckling action is produced, which results in furrowing at the bottom of stationary boilers.

"In locomotive boilers the buckling at the longitudinal seams, in the cylindrical portion of the shell, arises from its not being of true circular form in the vicinity of the overlaps. The tendency of the internal steam pressure is to correct this, and to induce a true circular form, and thus a cross strain, which may be correctly termed a 'girder strain,' is put upon the plates at a short distance on each side of the line of rivets; from this a change of shape ensues, which constantly varies with the pressure of steam. The position of the furrows is found to be that of greatest elasticity, being midway between the fixed ends of the fire-box and smoke-box, just where this buckling action would have most play. It will at once be seen that the thicker the plates the greater the leverage of the girder action, and thus to thicken their edges is only to aggravate the evil. The true circular shape may be maintained, as far as appearance is concerned, by substituting a butt-strip for the overlap, but this, from its one-sidedness, will not prevent the girder action, and, indeed, tends to make two furrows instead of one. Were an inner as well as an outer butt-strip introduced, the parts would be in equilibrio, and the strain then passing through the centre of the plates, they would be subjected to their legitimate tensile strain only, and the buckling action in question set at rest.

"But whatever expedients may be adopted to meet special cases, as one after another may force itself upon attention, some general precautionary measure appears to be needed to guard against the subtle influence of corrosion. It is often found, in a line of one hundred rivets, to attack ten and neglect the remainder; in an entire boiler, it will affect one or two plates and not the rest; and even in a series of boilers will select one in preference to the others. No doubt careful analysis might detect some predisposition in the metal, and thus account for the apparent anomalies, but the difficulty of foretelling the precise course of corrosion must be candidly acknowledged, and hence the necessity, as just stated, for the adoption of some sweeping precautionary measure, which will embrace every case without distinction.

"The association meets the difficulty with its own members by affording them the opportunity of having what is technically termed a 'thorough examination, of each of their boilers once a year, when all the seams as well as the surfaces of the plates, both outer and inner, are examined throughout, provided that the boiler is suitably prepared for the inspection. The conviction of the importance of these examinations — which such explosions as the one under consideration serve to deepen—may explain the frequency with which reference is made to this subject. Indeed, the association cannot hold itself responsible for the safety of any of the boilers under its charge, where the opportunity of making an annual 'thorough examination' is withheld. In addition, it recommends to those members using multitubular boilers, that such an arrangement of tubes should be more generally adopted as will admit of a man's gaining access between them and the shell for the purpose of examination, while those should apply the hydraulic test annually, who are employing boilers which will not admit of complete examination.

"From the experience derived from the boilers under the inspection of this association, it certainly appears hazardous to allow locomotives to work, as is very usually done, for five or seven years, without a complete internal examination; and it therefore becomes most important, either that some searching test should be adopted that shall at all times ascertain the sufficiency of the boilers without removing the tubes, or else that their construction shall be so modified that the parts may be rendered accessible to complete examination. The occurrence of four explosions to locomotive boilers, from internal corrosion, within the last eighteen months, must show the necessity of taking this subject into serious consideration."

SETTING BOILERS.

"Considerable difficulty is experienced in examining many boilers from the contracted area of the flues; some, indeed, are altogether inaccessible. Boiler-setting appears to be left too much to the individual tastes of the bricklayer, and, consequently, flues of every variety of proportions are met with. A sketch has been drawn up of the proportions most generally approved, and at an early opportunity a description will be given—which space does not now permit—for the assistance of those who are re-setting their old boilers or laying down new ones; meanwhile, a drawing lies at the office of the association for the inspection of members.

"L. E. FLETCHER, *Chief Engineer.*"

SHIP BUILDING.

DUMBARTON.—The ship-building trade at this port is in a busy state; the principal yards have their full complement of hands, and in some cases shifts are resorted to in order to the quick completion of the orders on hand. The engineer and foundry establishments are also in full operation. On Saturday afternoon, Messrs. William Denny and Brothers, famed for their superior iron screw steamers, launched a handsome vessel of that class from their south yard. Her dimensions are—length of keel and forerake, 255 feet; breadth of beam, 33 feet; depth of hold, 27 feet; and 1,360 tons builders' measurement.

MONKWEARMOUTH.—Messrs. G. S. Moore and Co., of Monkwearmouth, launched, on Wednesday last, a beautifully-modelled clipper barque, of 290 tons, named the "Agnes Holt." She is built on the mixed wood and iron, or combination plan, as it is called, and is the first constructed on this principle in the North of England. Mr. James Laing has also launched a splendid iron clipper of 612 tons, 12 years' class, called the "James C. Munro," sold to Messrs. George and John Munro, of London. She is 170 ft. long, 28 ft. beam, and 18½ ft. depth of hold. She is fitted with iron masts, Cunningham's patent topsails, &c.

THE MERSEY.—PROGRESS OF THE GOVERNMENT SHIPS, &c.—On Saturday, several ships were launched from the Liverpool and Birkenhead sides of the Mersey, Mr. John Laird's yard turning out a splendid Government troopship, called the "Orontes," and Messrs. Jones, Quiggins, and Co.'s yard two very fine vessels for merchant service. The Birkenhead Ironworks present a busy scene. There are from 2,800 to 3,000 hands in daily employment, and between 16,000 and 17,000 tons of shipping, warlike and commercial, in course of construction on the premises. Amongst the most prominent undertakings is the iron-clad screw frigate "Agincourt," which is intended for the royal navy. In another part of the yard, the two iron-plated rams, about which so many extraordinary rumours have been afloat, are rapidly getting into form, and to nautical men a very uncommon form it appears to be. With regard to the "Orontes," she is one of the improved class of troopships, of which the Government are building several—something after the style of the celebrated "Himalaya," but from 25 ft. to 30 ft. shorter than that vessel; her dimensions being—length, 300 ft.; beam, 44 ft. 4 in.; depth of hold, 22 ft. 6 in.; measurement (old) 2,811 tons. The engines—some portions of which are already on board—will be of 500-horse power, and are being manufactured by Messrs. James Watt and Co., of Birmingham. They are calculated to drive the ship at a high rate of speed, and the sailing capacity of the "Orontes" will be that of a barque full rigged in proportion to her tonnage. The "Orontes" is calculated for the conveyance of 1,200 troops and 70 officers. She will carry two pivot guns for defensive purposes, but must not at all be considered as a fighting ship. It is expected that she will be ready for service by the middle of February.

THE CLYDE.—Messrs. Burns have contracted with Messrs. Caird and Co., of Greenock, for two paddle steamers for the Royal Mail line between Glasgow and Belfast. Messrs. Napier are also occupied with a paddle for the same line, on which a new fleet will be engaged before 1863 has run its course. Messrs. L. Hill and Co. have just launched, at Greenock, a screw of 600 tons, built for the Calcutta and Burmah Steam Navigation Company. The vessel has been named the "Bussorah," and she is now being engined by Messrs. A. and J. Inglis, of Glasgow. Mr. A. Denny has completed a paddle named the "City of Dunedin," which is to be fitted with engines of 100-horse power, being intended to be employed by a colonial firm in the New Zealand trade. "The City of Melbourne," built by Messrs. J. and G. Thompson for the Australasian Steam Navigation Company, attained on her trial trip a speed of thirteen knots per hour; her burden 900 tons is builders' measurement, and she is 250

ft. long by 28 ft. beam, and 17 ft. depth, being fitted with a pair of four piston-rod geared engines. Messrs. W. Denny and Brothers have contracted to build for the Spanish mail service, through Messrs. A. Lopez and Co., of Alicante, a duplicate of the large and powerful vessel arranged for two months since. The steamers will be each of 2,000 tons burden, and will have 500-horse engines. Mr. A. Denny is also under contract to build a screw steamer for the Spanish coasting trade. The King of Burmah, calculating on the abolition of frontier duties, and the consequent probability of an increase of trade in his dominions, has ordered two powerful river steamers. He has also ordered a sea-going steamer, which is to ply in the Bay of Bengal. The contract has been taken by Messrs. A. and J. Inglis, through Messrs. Halliday, Bullock, and Co., of Rangoon. On the whole, the prospects of Clyde ship-building for the ensuing winter are considered tolerably satisfactory.

THE RIVER DEE.—The Roodee Ship Building Company has not been idle on the Dee. Saturday last witnessed the launch of a splendid new iron ship from the yard of that company, before an immense multitude of spectators. The following are the dimensions of the vessel, which is named the "Robinson Crusoe":—Length between perpendiculars, 202 ft.; extreme breadth, 34 ft.; depth of hold from floor, 23 ft. 3 in.; burthen, 1,116 tons, builders' measurement. Classed A 1 for twelve years at Lloyd's and at the underwriters.' The ship is intended for the East India trade, and has been built for Mr. M. I. Wilson, Hargreave's-buildings, Liverpool, who, we understand, has sold her to Mr. James Beazley, merchant, of the same town. The three lower masts and bowsprit are made of iron, and the lower yards of steel. The iron masts act as ventilators to the hold of the ship, having an inlet for air at the head, and a delivery for the same at the heel. The whole cabin arrangement is entirely on the upper deck, having the space below for cargo alone. All the channel plates are secured to the sheer strake inside. By such arrangement the vessel shows a complete flush outside. The Roodee Company has now on hand three large iron ships of 1,000 tons each builders' measurement.

The Company are also building a large iron parallel lift, or floating dock, for Messrs. Rose and Crowder, of London. It is to be erected in the London Docks, and it is anticipated that this dock will be a great acquisition to the shipowners of London, where dry dock accommodation is much needed. The dimensions of the dock are 190 ft. long, 60 ft. broad, and 17 ft. deep. The arrangements for lifting the dock after the vessel is floated on it are very simple, and are the patent right of Messrs. Rose and Crowder. The dock consists of a rectangular iron vessel, or pontoon, of proportionate dimensions, for lifting and carrying vessels of any size, which is lowered or sunk (by admitting water at pleasure) to the required depth for floating over it the ship to be lifted, and the ship being properly placed over the blocks, and shored in the usual manner, water equal to the weight of the ship is pumped out of the pontoon, and it is raised with the ship upon it. After the sighting, or repairs, are concluded, water is again admitted to the pontoon, which sinks, and the vessel is floated off. The rapid action of this system of dock, by which vessels can be raised for inspection in from 15 to 30 minutes, and floated again in as brief a space, together with the full exposure to light and air, enabling sighting and repairing to be conducted with such perfection and despatch, are amongst the more prominent of its many advantages. A working model of this dock has been exhibited in Class XII. of the International Exhibition, and been awarded honourable mention for novelty and simplicity of design.

THE THERMOGENERATOR.—A machine is being tried at Marseilles, called the "thermogenerator," in which the heat to be used in distilling is obtained by means of the friction of two surfaces. The steam and boiling water required are thus obtained without the direct use of fuel.

BOAT LOWERING APPARATUS.

THIS journal for years past has paid rather more than ordinary attention to Clifford's and Kynaston's systems for lowering and disengaging boats. After giving those rival systems the most impartial investigation, we were obliged, in obedience to principles and facts, to accord the largest meed of praise to Mr. Clifford for his invention. We arrived at this conclusion from no partiality. Indeed, were we inclined to be partial, our feelings would have induced us to advocate the late Captain Kynaston's system for the sake of his widow. Considerations of humanity and a strong conviction, however, prevented our doing so. We therefore share in the surprise which has been expressed by many naval officers at the tenor of a recent order issued from the Comptroller's Department of the Navy, directing that all new ships of war shall have their boats fitted exclusively with Kynaston's disengaging hook. We consider this order to be arbitrary and unjust. When a legitimate difference of opinion existed, the very least the Comptrollers could have done would be to have left the shipbuilder or officers of the ship to decide for themselves. Why impose such a condition when so many conscientiously consider that Clifford's system is the completest and the best? We assert, with the *Times*, "that Mr. Clifford's boat lowering apparatus has rendered good service in too many instances to be thus disposed of," and that the Comptroller will have to reconsider his decision preparatory to its revocation.

RAILWAY ROLLING STOCK.

A FEW days since Mr. W. Johnstone, President of the Institution of Engineers in Scotland, in his inaugural address, alluded, as a matter of course, to the International Exhibition. In the production, said that gentleman, of metals, chemicals, glass, and earthenware, and of all ordinary woven fabrics, we have undoubtedly distanced all competitors, with some very few exceptions. In the case of machinery, the department more peculiarly interesting to engineers, it may be said without exaggeration, that we have been first. There certainly is no comparison between our locomotives, our marine and land engines, our spinning and weaving machinery, our sugar-mills, and our tool making machinery, and those exhibited by our rivals.

Among the few exceptions referred to are railway carriages and their fittings, cast-steel forgings, and some of the unusual forms of rolled iron. It has long been matter of common remark, that the carriages of foreign railways were better and more comfortable than those of a similar class with us. This may be partly explained by the large proportion of old and badly-constructed stock still kept up by many companies in this country. But even allowing this, it must be admitted that foreign stock of railways is fully superior to our own; and there can be no doubt that the best foreign carriages exhibited were fully equal, if not superior, to those of English make. Many reasons have been assigned for this, but they may all be resolved into the simple fact that our foreign rivals have paid more attention than we have done to the proportions and quality of the fittings, and to the excellence of the workmanship in every minute particular. It is impossible to over-estimate the importance of attention to these points, not only as regards the comfort of passengers, but also as regards the question of economical working. Repairs and renewal of rolling stock form a very large portion of the working expenses of a railway; and to use stock after it becomes ripe for renewal is not only severe upon itself, but is equally injurious to the permanent way. The rail and the wheel are, in the words of Stephenson, "man and wife," and you cannot injure or depreciate the one without doing corresponding damage to the other. This great truth is now fully recognised in railway management, and is shown by the increased attention which is being paid to the improvement of rolling stock and of the permanent way; and I hope that such attention, coupled with the natural decay of old and objectionable rolling stock and its renewal, will soon enable us to surpass all continental railways in these all-important matters.

It must have struck every one that foreign carriage-fittings in iron, more especially those from France, were also fully equal to ours. They were certainly lighter, and very well made; and he was surprised at being informed that they were actually cheaper than with us, being only on an average 2½d. per lb. This is a somewhat astonishing result, if we consider that the raw material is 25 to 40 per cent. dearer in France than in Britain. We have almost all the materials for iron-making—the ore, the coal, and the lime, lying in close juxta-position, so that with us the cost of raw material is very small indeed. But in France they are widely separated, and the extra cost of carriage, compared to what it is with us, raises the price of pig-iron from 60s. to 90s., and of bar-iron from 130s. to 170s. per ton. It is very much to the credit of the French manufacturers that they can, in the face of this great difference against them, produce iron work of first-class quality as cheaply as in Britain.

They also produce angle iron, T-iron, and I-iron of extra sizes for smaller extra charges than those made by our makers; and they have carried the manufacture of these extra sizes and forms much farther than we have done; and he understands it is the case that many of these sizes and forms must be ordered by our Glasgow iron merchants from French and Belgian makers, and the prices are so low that I-beams, 12 in. deep, cost only £12 10s., and when 2 ft. deep, £20 per ton. There is no doubt that the advantages we possess for ordinary sizes and qualities, with proper skill and attention, ought to be carried into every branch of the manufacture. Were this done our foreign trade would be greatly extended, and the use of iron would be adopted to a larger extent in many kinds of industry.

A good deal of the uncertainty attendant on the introduction of iron-making, arises from the obscurity which still surrounds many of the chemical changes that take place in its various stages. This obscurity can only be removed by accurate experiments on a large scale.

THE GOVERNMENT INSPECTOR UPON EXPLOSIONS OF GAS.

MR. MATHIAS DUNN, the Government Inspector of Mines for the North of England, in his latest pamphlet entitled "How to prevent Accidents in Coal Mines," says that, although explosions are not so extensively fatal as falls of roofs, yet they come upon the public mind with more appalling effect, because the calamity is sudden, is generally unlooked for, is attended with numerous deaths, and the grief extensively circulated amongst friends and relatives, many of whom are left unprovided for; inasmuch as they not only include a number of persons by the same stroke, but for the damage done to the mine, and the time required for the restoration of the ventilation, so that great delay often takes place, attended with prolonged anxiety and excitement, independent of the loss of life from the after-damp arising from the explosion.

Much delusion often prevails regarding the actual state of that part of the mine were the explosion originates, which may be altogether at variance with its general condition; therefore it will be well to particularize some of the chief circumstances in such a case.

1st. The colliery may be generally deficient in ventilating power in regard to the aggregate column.

2nd. The general ventilation may be unobjectionable; but it may be either too much diffused, or ill arranged, and inadequately guided.

3rd. However well arranged, in a general point of view, each working place may require the aid of brattices and doors to carry off the gas discharging from the coal, and this again demands adequate attendance.

4th. These doors and brattices may be ill-constructed, or may be formed of small coal, or canvas, or neglected to be carried forward sufficiently near the face.

5th. Some unusual discharge of gas from a blower or bad coal may overpower the air, which is ordinarily sufficient.

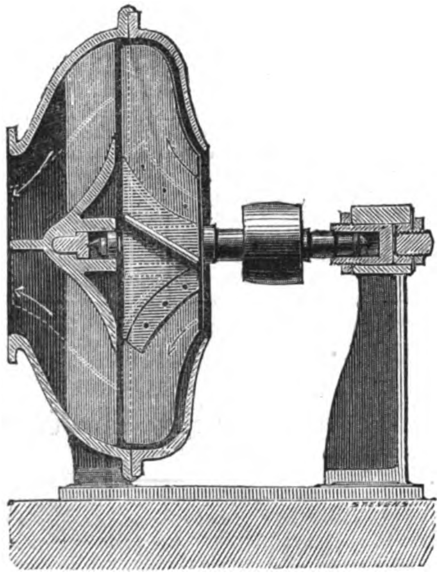
6th. Falls or stoppages may take place in the workings or the waste, so as to derange or adulterate the air, and so take the naked lights by surprise.

7th. Often the use of safety lamps is left to the management and discretion of the colliers. Where they are agreed to be necessary, they are often suffered to become imperfect, and to go unlocked, as also to be opened for the purpose of blasting the coal, which not unfrequently leads to mischief, whilst the colliers sometimes covertly draw the flame through the gauze to light their pipes.

8th. The mischief of after-damp is greatly increased if the excavations wherein the bearing stoppings are placed be wide—if the stoppings are built of wood, or made of small coal. Therefore, in all well-regulated collieries, the permanent stoppings are built of brick or stone, plastered with lime, and supported by several yards of stowing.

PETRIE'S IMPROVED BLOWER OR FAN.

THE accompanying engraving shows in section a view of an improved blower, recently patented by Mr. J. Petrie, of Rochdale. The invention



consists in placing the blades on the revolving spindle, at an angle so as to throw the air off in the direction of the axis, after which it passes to a conical or other shaped chamber provided with partitions, so as to form a number of compartments.

LIGHTNING CONDUCTORS.

ACCORDING to a correspondent of "Cosmos," each of the two columns of Antonine and Trajan at Rome, sustains a colossal bronze statue, and the columns, not being in a state of conduction with the earth, are in danger of being injured by lightning. In fact, accidents have already happened, but as yet without causing any great damage. The preservation of these monuments is a matter of interest to the whole civilized world, on account of their historical value. Their precarious state is such that Napoleon III. has lately had a complete model of the column of Trajan made for his own use in writing the biography of Cæsar. Professor Volpicelli, in 1848, proposed to protect these structures by means of a conductor, arranged like the one on the Duke of York's column. From various reasons, political and otherwise, this has not been done.

Some persons have urged that the best plan would be to use a number of lightning conductors placed on the surrounding buildings. It has, however, been shown that this indirect protection is worse than useless, being, in fact, absolutely dangerous. Professor Mossotti has, on this subject, thus expressed himself in a recent paper on lightning conductors:—"If, instead of placing a lightning conductor *directly* on to the column, you place a series of conductors on the neighbouring houses, any given flash of lightning, instead of being deviated from its course, will be directed towards the column you wish to protect. The surrounding air, being in a low state of polarization by the action of the conductors, will absolutely prevent the lightning from taking a side direction." These observations are, of course, just as applicable to tall factory chimneys as to classical columns.

While upon this subject, we will give some extracts from a paper on Lightning Conductors, lately read to the Academy of Sciences of Paris by M. Calland. He states that lightning conductors are being made in France of thin brass wires. As is well known, the coefficient of conduction of this alloy is 12, that of iron 16, and that of copper being 100. Metals also get heated by the electric fluid in an inverse ratio to their respective powers of conduction. The chains of suspension bridges have been broken in this way. If brass be not so liable as iron to combustion, it is more fusible; and a conductor made of this material might get fused by a violent electric shock.

M. Calland states that he makes his cables of seven strands of copper wire there being seven wires to each strand; this number permits of the wires being twisted together with fewer intermediate spaces. He also states that the humid conductor of the ground is usually not made equal in conducting power to the one of metal. The custom is to untwist the end of the cable, and to place it into some water. The conductor having a sectional area of one square centimetre, its conducting power will be represented by 91,440,000; that of silver being 100,000,000. The relative conducting power of distilled water being only 0·0133, a moist surface of 700 square metres would be necessary in order to reach the conducting powers of the cable. In case of a violent shock, such a small surface as this would almost form an insulation. M. Calland proposes to place the end of the rod touching the ground in animal charcoal, and to surround the latter with a quantity of coke. These two substances are excellent conductors of electricity, and the porous nature of coke renders it admirably fitted to increase the surface of contact of the conductor.

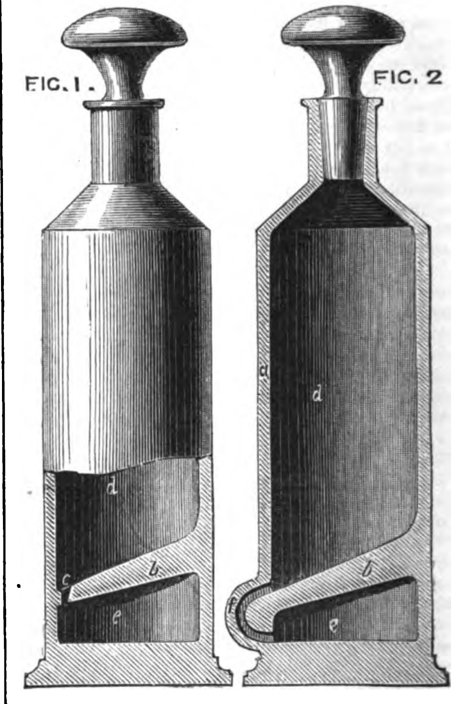
A SALT WELL.

ACCORDING to American accounts, a novel salt mine has been discovered at Wellsville, in the county of Columbiana, Ohio. A well was being sunk, on the artesian principle, for extracting rock oil, when, at a depth of 488 ft., a column of gas made its escape with such violence that the boring rods and some 200 ft. of piping introduced into the crifice were suddenly thrown out like a ramrod from a gun. The boring had reached an extensive vein of salt brine, and the gas continued to drive out with it a column of water charged with salt, and of the same diameter as the bore hole, to the height of 150 ft. This eruption lasted for six months, when it occurred to the proprietors to utilize the waters for the manufacture of salt. The gas itself being conducted into a furnace by pipes is lighted, and it then evaporates the water without any other fuel being used. The furnace is heated to a high temperature, and the flame rises above the chimney. It is seen from a distance of several miles round. The salt brine is delivered at the rate of about six gallons per minute, and furnishes one barrel of salt per hour. The gas is said to have a pressure of 126 lbs. to the square inch.

DREWETT'S IMPROVED BOTTLE.

MR. E. DREWETT, of Blackheath, has obtained a patent for a bottle having a partition near the bottom, for the purpose of separating and filtering the contents, as shown in the engraving. The sediment of the liquid in the bottle *a* is allowed to settle and pass through an aperture *c* in the

FIG. 1. FIG. 2



partition *b*, and retained in the space *e* between. Fig. 1 shows a partial section of a stoppered bottle, having a division piece or partition as above mentioned; and Fig. 2 is a view of a bottle in section having a bulge *f* in the side thereof, through which the aperture is made. Bottles so constructed may have their contents decanted, and the whole of the sediment retained in the lower chamber.

STRENGTH OF GUNS AND HOW TO CAST THEM.

THE *Journal of the Franklin Institute* contains an account of an important conversation which took place at a late meeting of the Institute, on the subject of the metal, the moulding, casting, and cooling of large cannon. W. W. W. Wood, Chief Engineer of the U. S. Navy, who was present, stated that very great difficulties had been experienced in the casting of heavy ordnance. It was found that guns made of highly elastic cast iron were capable af greater endurance than guns made of more dense iron possessing greater tensile strength. He had been connected with a set of experiments wherein it was demonstrated by practical tests that heavy pieces of ordnance, the iron of which was capable of withstanding from 39,000 to 40,000 pounds' tensile strain per inch, with a corresponding density of metal, were not capable of the endurance of similar pieces made of iron which did not sustain a tensile strain of more than 17,000 and 23,000 pounds per inch, and which was of less specific gravity or density. In the lattter case, one gun sustained, in addition te the proof charge, over 1,700 service charges with no perceptible enlargement except of the vent and slightly furrowing indentations leading to the same. This is certainly useful information on this subject, as it has generally been held that the most dense cast iron was the best for guns of all sizes. Chief Engineer Wood also stated that the accepted theory as to the cause of the breakage of heavy guns was, that in the ordinary method of casting and cooling, the exterior portions on cooling first produced a strain by unequal shrinkage in the mass. Cap-

tain Rodman's method of casting large guns hollow, and cooling the interior with a stream of water passing through the hollow core, is intended to obviate this evil, by equalizing the shrinkage on the inside and outside. Captain Dahlgren's method to obviate t e evil consisted in casting the gun more nearly in the form of a cylinder, then turning off the additional metal on the exterior which had caused the strain in unequal shrinkage, by having been first cooled in the mould. His guns were cast solid, then the interior part, supposed to be the weakest, is bored out. The new 15-inch Dahlgrens for our armour-clads are cast hollow and cooled upon Captain Rodman's principle, but their rough form approaches to that of a cylinder 38 inches in diameter at the [illegible], which i afterwards turned off [illegible] in. All the English 13-inch cast-iron mo[illegible] used in the bombardment of Sweaborg [illegible] in two equal halves after an average of [illegible] rounds. The age of a gun has much to [illegible] its durability; the older it is, the gre[illegible] number of charges will it withstand before [illegible]. Chief Engineer Wood believes the great cause of bursting in heavy ordnance is owing to unequal expansion between the interior and exterior portions of the gun when being rapidly fired. The interior is first heated before the exterior acquires a corresponding temperature. A strain by such unequal temperature is exerted upon the gun equal to the difference of expansion due to the difference of elongation of the masses of iron. The gun which exploded on board of the *Naugatuck* afforded proof for entertaining this opinion.

Mr. John W. Nystrom, who was present, stated that it was a bad practice to cast a gun solid and turn off several inches of the exterior afterwards, according to the method adapted for the smaller Dahlgren guns. The strongest part of the gun is thus turned off. He had made experiments in Russia with cast-iron bars 1 in. square and 2 ft. long. One bar was cast the correct size, and the other cast 2 in. square, then planed off half an inch on each side, reducing it to 1 in. The lateral strength of these bars was carefully tested, when it was found that the one which was not planed was 25 per cent stronger than the other. He had made cast-iron rollers for rolling angle irons, which were so correct that when taken from the moulds and centered in a lathe there was but a mere trifle of work to be done by the tool. The mould was turned in the flask with an iron sweep of the correct shape of the roller, and no allowance made for turning the roller when cast. Since his return from Russia he had seen similar rollers moulded with wooden sweeps at Phœnixville, Pa., and about ⅛ths of an inch was allowed for turning off in the finishing—just enough to take away the most valuable part of the roller. The mould should not only be formed by an iron sweep, but the blocking and finishing ought to be accomplished with the same instrument and the finishing of the roller could afterwards be effected by simply grinding with emery, and thus the strongest part of the casting retained. This is the principle upon which Mr. Nystrom proposes to mould and cast guns. He believes that rifle guns may be cast so perfect that they can be taken direct from the foundry and used in active service. He would employ Rodman's process of cooling the gun from the core for the purpose of hardening it, and would then cool the entire gun by the mode in use for annealing the Whitney car-wheel, by allowing one day for cooling each inch of calibre, or 11 days for an 11-inch gun. When the gun has cooled down to 400 deg. Fah., it should be lifted from the pit, the muzzle closed with a wooden plug to prevent the air conducting away the heat from the bore, and the outside should be cooled with water to the temperature of the atmosphere. No water should then be permitted to get inside. The object of this last cooling operation is to give the metal in the bore a slight tensile strain, while that on the outside is slightly compressed. When a gun thus made would become hot by firing, there would be the least strain in the metal by shrinkage, and a very strong gun would thus be secured. Formerly, iron guns were cast finished on the outside—they were, at least, seldom turned.

Legal Intelligence.

BETTS V. MENZIES.

This is the great patent case, in which the House of Lords have recently given a decision of, perhaps, greater pra[illegible] not merely to that large class of per[illegible] of inventions, but to that still larger [illegible] deeply interested therein, the commercial community and, indeed, it may be said the community at large; the point decided, in [illegible], being that not the man who originally, [illegible] matter of mere scientific theory or suggestion, hit upon some idea of the invention, but the man who first makes it commercially practicable and of practical value to the community, is entitled to patent it. The action was upon a patent obtained by Betts, the plaintiff, in January, 1849, "for a new manufacture of capsules, and of a material to be employed therein, and for other purposes." The action, for its infringement by the defendant, was brought in March, 1857, and tried before Mr. Justice Erle and a special jury in January, 1859. It was proved that by following the [illegible] contained in the plaintiff's specification, a workman of ordinary skill could produce the manufacture therein described, and that the same was a useful and valuable article of commerce. It was set up on the part of the defendant that the plaintiff's invention, or some part of it, was included in the specification of a patent granted to one Dobbs, so long ago as the year 1804. On the other hand it was contended, on the part of the plaintiff, that it was impossible to ascertain the meaning of Dobbs's specification without evidence, and that its practical effect was for the jury upon such evidence; that Dobbs published nothing which could give any practical knowledge of the invention [illegible] pended on the combination of lead and tin), but that, on the contrary, that which he had published actually, instead of leading to the discovery, misled and led away from it, and that it was open to the defendant to prove all this by evidence before the jury, for them to determine thereon as to whether there had really been any practical discovery and disclosure of the invention by Dobbs, the alleged prior inventor. Mr. Justice Erle in effect so held, and left the evidence to the jury, who found in favour of the plaintiff. There was then a rule for a new trial, on the ground that the verdict was against the evidence, or to enter the verdict absolutely for the defendant as a matter of law, on the ground that such evidence was not admissible, and that in law Dobbs's specification was a discovery and destroyed the novelty of the plaintiff's invention. The Court of Queen's Bench made the rule absolute to enter the verdict, on the latter ground, for the defendant; the rule for a new trial, on the former ground, standing over. The Court of Error, in July, 1860, upheld this decision; but the House of Lords last session reversed these judgments, and thus upheld the original direction of the learned judge who tried the cause, Mr. Justice (now Lord Chief Justice) Erle, and likewise affirming the correctness of a similar ruling by Mr. Baron Bramwell on the trial of the great gaslight patent case—"Hills v. the London Gaslight Company." Pending this litigation, one of the Vice-Chancellors (Wood) had given the plaintiff an *interim* injunction; but, on the judgment of the Court of Error affirming that of the Court of Queen's Bench, his Honour dissolved that injunction, being of opinion that, as wise judges had decided against the patent, it was not proper to continue the injunction merely because an appeal was pending to the House of Lords. And meanwhile, on the 8th of June, 1859, on the judgment of the Court of Queen's Bench being given in favour of the defendant, he signed judgment in the action. Afterwards the House of Lords reversed the judgment. Thereupon in this term Mr. M. Smith, Q.C., on the part of the defendant, got a rule to re-enter the case on the new trial paper, to have it argued on the ground which had been reserved, viz., that the verdict was against the evidence.

After a long argument between the counsel on each side,

The Court—though with great doubt—said they thought that upon the whole there was no sufficient ground to deprive the defendant of his legal right to have the case re-argued upon the effect of the evidence. They had little doubt that the defendant had meant to treat the judgment as final, and had not intended to "have two strings to his bow," and reserve the effect of the evidence, but relied rather on the probability of the judgment of this court and the Court of Error being affirmed by the House of Lords. As, however, they did not think that the plaintiff had been at all prejudiced, and were of opinion that the Vice-Chancellor would have taken the same course had all the facts been before him as they now stood, they could not [illegible] case being re-argued on the [illegible].

It was intimated that the [illegible]re reading of the evidence (the case having [illegible] six days to try), would take so long a time that the [illegible] must be put off till next term.

THE PNEUMATIC DESPATCH COMPANY.—The transmission of parcels and small goods from [illegible] to station, through a confined iron tube by [illegible] atmospheric exhaustion and pressure, will [illegible] commenced. The London and North-Western Railway Company having granted a site for the [illegible] and receiving-house, rent free, at Euston-square, a few yards from the Clearing-house; the d[illegible] of the Pneumatic Despatch Company [illegible] commenced operations by laying down [illegible] the road-way of Upper Seymour-stre[illegible] iron tubing about half-a-mile in length, [illegible]ending from that terminus to the post-office in Eversholt-street, under the superintendence of their engineer, Mr. T. W. Rammell. Within the iron tube, which is about 2 ft. 9 in. high, and 2 ft. 6 in. wide (its section being similar to that of a railway tunnel in minature), are two small ledges, or rails, on which the wheels of the small cars bearing the parcels will run. These will be propelled backwards and forwards, on the signal being given, by the exhaustion and pressure of the air in the tube. The immense disc and chamber in which it revolves have been removed from Battersea, and are being erected within the walls of the station and receiving-house. The disc, or wheel, is 21 ft. in diameter. It is composed of three sheets of [illegible] the [illegible] which form the outside [illegible] about [illegible] eighth of an inch in thickness, while [illegible] centre and smaller [illegible]n inch thick. These are screwed on to [illegible], which radiate from the centre of the wheel, [illegible] form 32 cavities, there being a distance between the plates at the rim of nearly two inches. Air chambers pass beneath the disc, which are exhausted by [illegible] revolutions in the race chamber. The wheel will be worked by a diagonal direct acting high-pressure engine of about 15-horse power. As regards the speed which will be attained, the railway company have only stipulated for a *minimum* of 15 miles, but from experiments it has been shown that a speed of 35 miles can be attained. [illegible] no doubt, will prove a most important acquisition to the Post-office in the quick delivery of the mails. A number of workmen are now engaged in the construction of this line, which is expected to be finished in about a month's time. Arrangements have been made with Messrs. Pickford and Co., who have offered a site for the proposed station in Gresham-street, at a small rent. It is also proposed to form stations at Smithfield and Holborn-hill, which will be suitable for the large and small parcels traffic.—*The Times.*

The dredging of Portsmouth Harbour is likely to afford permanent and successful results. Three years since the depth of water at low water spring tides was 12 ft. 6 in.; but in the early part of the present year it has been increased to 17 ft. giving a depth of 27 ft. at high water neap and 30 ft. at high water spring tides. The great advantage to be gained will be that ships of the largest draught will be able to pass in and out of Portsmouth harbour at high water every day in the year.

At the last meeting of the Royal Geographical Society, a letter by Dr. Livingstone, and his brother, Mr. Charles Livingstone, on the Lake Nyassa in Africa, was read by Dr. Norton Shaw. After describing the settlement of the Oxford and Cambridge Mission, the letter gave an account of the exploration of the Lake Nyassa. They took several soundings, the greatest depth obtained being 696 feet. The natives were, upon the whole, civil, and the population dense. The exploring party was obliged to turn back, although in sight of the large mountain masses to the north, in which Dr. Livingstone thinks it probable the lake ends, in consequence of the land party having fled, the provisions being expended, and the land desolated by the slave-trading expeditions from the coast. The whole distance of about 600 miles, going and coming, was accomplished in about three months. The doctor and his party were about to carry a small steamer, in pieces, past the Murchison Cataract, in order to navigate the lake, which was nearly 200 miles long, with a breadth of about 50 miles.

VAILE'S IMPROVED PROPELLERS FOR SHIPS AND BOATS.

FIG. 1. FIG. 3.

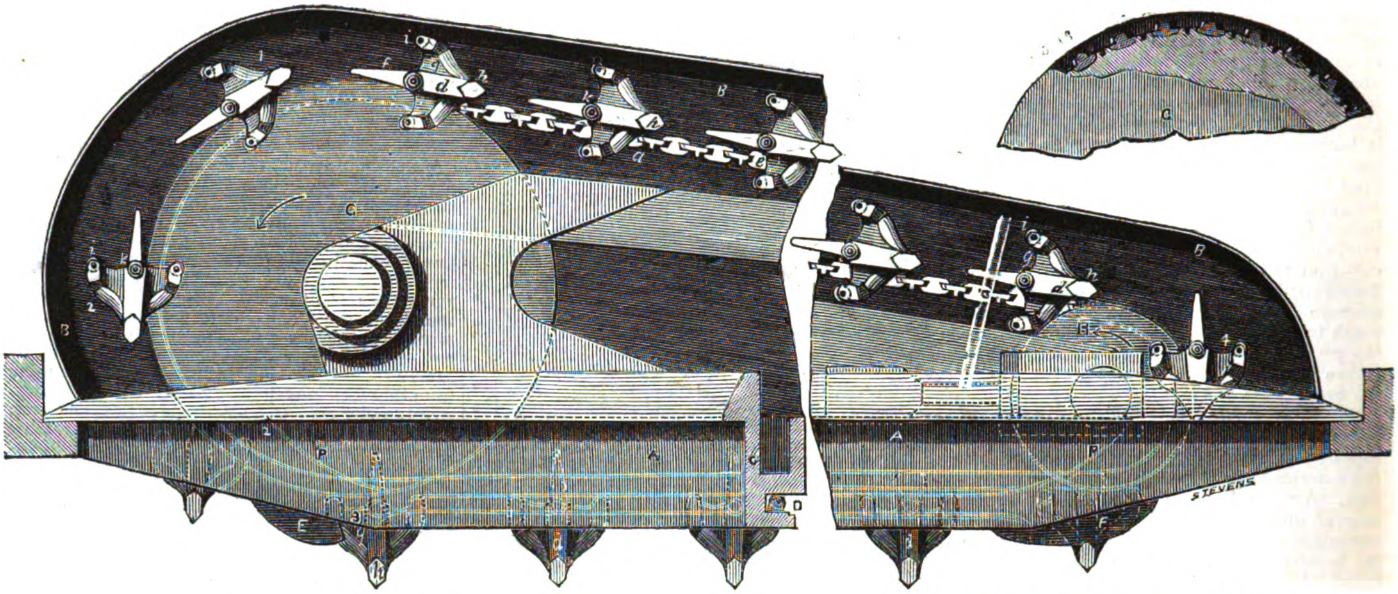


FIG. 2.

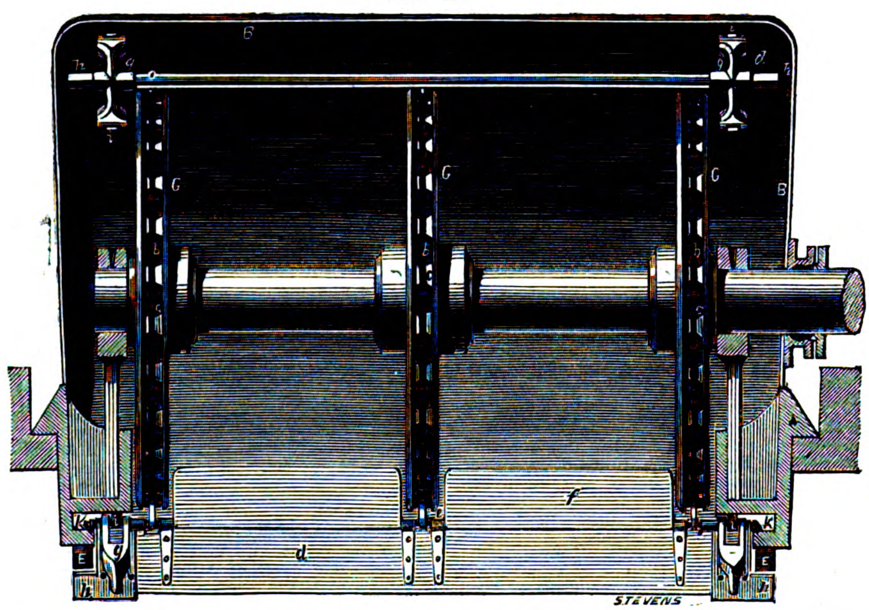


VAILE'S IMPROVED PROPELLERS FOR SHIPS AND BOATS.

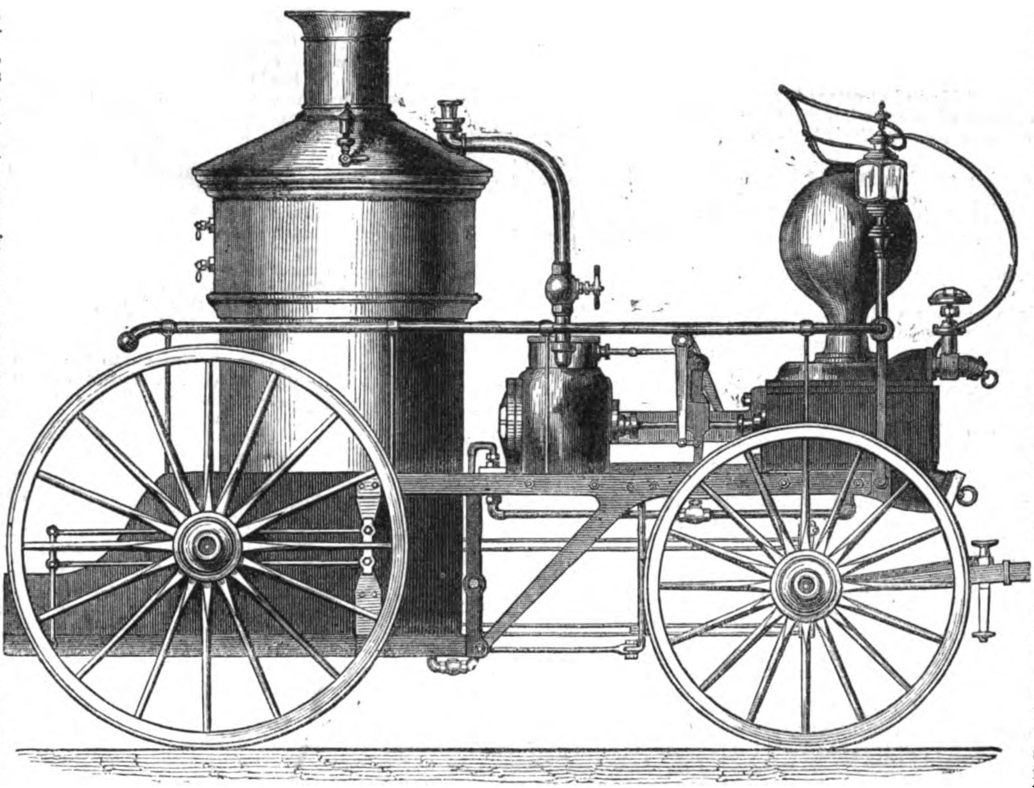
This invention, recently patented by Mr. R. Vaile, of Maida-hill, and Auckland, New Zealand, consists of endless chains of peculiar construction, having floats attached to them. The chains and floats pass round collars or drums mounted upon shafts which are driven by steam or other power. Fig. 1 of the above engravings is a side view of the propeller. Fig. 2 is a transverse section of the same. Fig. 3. is a side view of a portion of one of the collars G. The whole of the floats and chains above the water line are enclosed in a suitable casing. The chains are made of flat links, each alternate link having a tooth *a* on its underside, which takes into indentations *b* formed in the collars, while the alternate links lie in suitable slots *c* as shown at Fig. 3. The floats *d d* are connected to the chains by means of links *e e*, forming part of the chain, and made with an eye for receiving a pin, secured to a float by straps. The upper parts of the floats *f f* have portions cut away to allow of their working between the collars G, as shown at Fig. 2. Each float *d* is furnished with projecting arms carrying rollers *i i*, and a central flanged roller *k*. The projections *h* act upon the guide E, and prevent the floats entering the water in a wrong position. A is the lower frame, which is to be fixed to some part of a vessel, so that the floats may work below the water line. B is a casing secured to the frame.

The inventor prefers to fix two propellers, one on each side of the keel, and at or about the centre of the ship. The frame A is formed with double sides C C, and with a groove D, with surfaces for the rollers *i* and *k*, to travel on. The frame carries the bearings for the support of the shafts and collars. The collars H are of less diameter than the collars G, but are otherwise similar, the chains are carried round the collars G and H in the direction of the arrows, and for the purpose of keeping the chains tight, the bearings for the collars H are free to slide in slots. They may be acted upon by jacks or otherwise. Upon rotary motion being communicated to the shaft of the collars G the floats are caused to move and assume the position shown at Fig. 1. When travelling along the upper part of the frame, the floats lie parallel with the chains, the flanged rollers *k* resting upon rails formed to receive them. As soon as each float reaches the point marked 1, it commences to alter its position; and when it reaches the point marked 2, whether it descends in the reversed position or not, then its arms, coming into contact with the curved ends of the guides P or E, it assumes the position marked 3, and is made to retain that position by rollers *i i* coming in contact with bottom of the upper surface of the groove D, and the central flanged roller K coming in contact with the flange. In this position the floats are maintained until they are feathered to leave the water. This feathering is effected by the pressure of the water and the contact of the appliances attached to the floats and guides. The floats then assume the position 4, and afterwards lie parallel with the chains. In order to "go astern," it is simply necessary to reverse the engine, thus changing the direction of rotation of the collars and chains when the same positions will be assumed by the floats passing over the smaller collars H, and in their course from those collars to the collars G, as were assumed by them when propelling "ahead," as before mentioned.

The engineers have completed the survey of the proposed railway from Crieff to Comrie. The line will pass through the Crieff meadow, thence aross the Turret, and along by Sir David Baird's monument on the north bank of the Earn, till it reaches a field at the east end of the village of Comrie. The promoters propose to make the terminus at the east end of the village, for by doing so the railway would not require to be put across the rivers Lednock or Earn, which would effect a saving of at least £1,200.

At the last monthly meeting of the Northern Institute of Mining Engineers, the president, Mr. Nicholas Wood, congratulated the members on the decision arrived at by the Council of the British Association to hold their next annual meeting at Newcastle, and said it would be incumbent on that institute to take steps to add to the success of the meeting. There was much of great interest to be seen in the neighbourhood, and he was sure that it would be of great pleasure to all present to aid in showing every attention in their power. The annual meeting of the institute, which was held in Birmingham last year, was so successful that it was then determined to hold these aggregate meetings frequently, and as the British Association would meet in Newcastle next year, it perhaps would be considered advisable to hold their next aggregate gathering here at the same time.

LEE'S IMPROVED STEAM FIRE-ENGINE.



THIS machine, manufactured by Messrs. Easton, Amos & Sons, was subjected to a severe trial test on Monday last, in Mr. Hodges's distillery ground, Lambeth. It is patented by Mr. Wellington Lee, of the firm of Larned and Lee, New York. In producing the machine particular attention has been given to the following points:—Lightness, compactness, and portability, and the obtaining the utmost possible amount of pumping power upon a machine which can be conveniently handled by two horses. Time of getting up steam, and getting generally into operation. General safety, and the greatest amount of security obtainable against derangement in transit or accident in actual work at a fire.

One of the chief points in this engine is its arrangement as a duplex engine; the piston rod of one steam cylinder actuating a lever wheel opens a steam slide valve of the other cylinder; and by a peculiar arrangement of the parts, the end of the stroke of each is turned upon a cushion of steam. By this means there is no dead centre about the machine; at the moment one piston is turning its stroke, the other is at its greatest force.

The proportions of the Engine E size are—

No. of steam cylinders	2
Diameter of ditto	9½ in.
Length of stroke	9½ ,,
No. of water cylinders	2
Diameter of ditto	5½ in.
Length of stroke	9½ ,,

The peculiar construction of the pumps employed enables all the valves to be readily got at, and further, in cases where quantity of water is mainly required, the pump pistons can be removed in a short space of time, and others of 6½ inches diameter substituted. The arrangement and construction of boiler admits of almost any amount of steam being obtained while running.

CAPTAIN COLES' IRON MASTS FOR SHIPS.

CAPTAIN COWPER COLES, of Southsea, whose inventions in shields for ships of war are well known, has just patented an improvement in iron masts suitable for ships of war as well as merchant vessels. The masts are constructed of a central and two side tubes of iron or steel. The tubes pass through and are keyed to the decks, the central tube being carried in a direct line, while the two side tubes extend from the central tube at their bases, and are carried up at an incline till they unite with the central tube at or near the upper part. The central tube is continued upwards to form the topmast, or a separate tube is fitted thereto. The mast becomes as it were self-supporting, and shrouds and other supporting rigging are dispensed with.

CAPTAIN COLES' IRON MASTS FOR SHIPS.

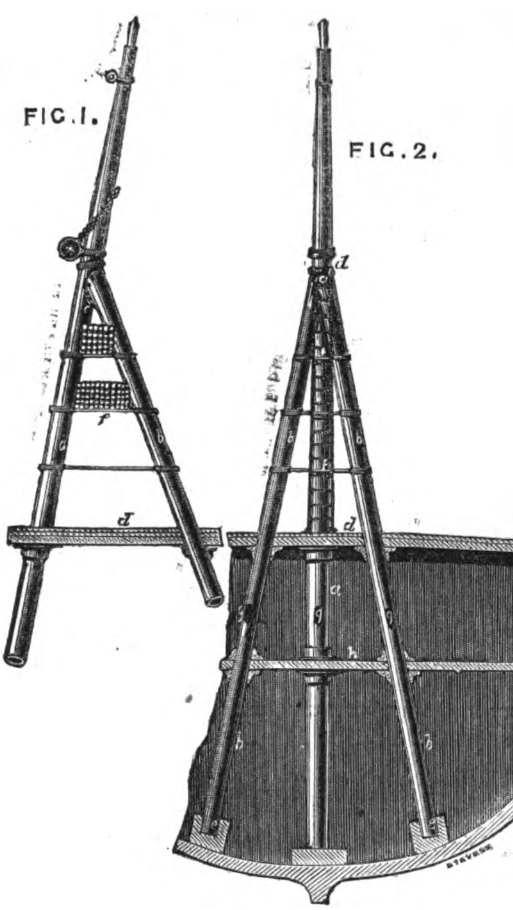


Fig. 1 of the accompanying engravings is a side elevation, and Fig. 2 a back view of a mast constructed according to this invention. *a* is the central tube of mast proper, and *b b* are the side tubes united to each other at their upper ends, and to the central tube by means of bolts passed through flanges or otherwise; *c c* are strengthening plates. The central tube *a* is continued upwards to form the topmast. The tubes are keyed to the deck *d*, the central tube *a* is carried down to and stepped to the "kelson," while the tubes *b b* are stepped in the "bilge" of the ship, as shown at *e e*, or they may be cut short, and secured to the lower deck *h*; *f f f* are tie rods for uniting the tubes, and for supporting a flooring, round which hammocks may be fixed as shown, to afford protection to riflemen stationed on the flooring; *g g g* are apertures in the tubes *a* and *b b*, through which ropes or chains for working the sails, which the inventor prefers to be fitted with Cunningham's patent reefing apparatus, may be carried to the lower deck *h*, in order that the men working the sails need neither be sent aloft nor exposed on the upper deck *d*. Cross trees may be fitted at the junction of the tubes, and a top for carrying a topmast may be added instead of the tube *a*, itself forming the topmast.

TO CORRESPONDENTS.

RECEIVED.—E. L., Capt. N., W. A., Capt. C. P. C., B. W., E. E. W., J. J. L., P. J., B. C., J. B., J. N., G. C., W. E., H. E., J. R. T., B. C.

S. H.—No doubt there are several efficient smokeless grates. We would refer our correspondent to our last number, where, in our article on "Locomotives," there is an account of two plans, and the general theory upon which the most of the coal-burning arrangements are based. A good fireman is a smoke-burner with any grate, and almost any kind of coal.

"NOBODY" (Holloway).—Your method of signalling appears to be a good one, but a patent was obtained by Mr. J. Fenton, of Low Moor, in 1856 (No. 2,520) for a similar invention. Unfortunately, there is no lack of inventions for signalling, but great unwillingness on the part of railway executives to adopt improvements.

We have been informed that Cutts, Sutton and Co. did not exhibit in the 13th class of the International Exhibition, as stated in our article on "Philosophical Instruments," on the 10th of October last.

Correspondence.

[*We do not hold ourselves responsible for the opinions of our Correspondents.*]

INVENTION BY NAPIER, OF MERCHISTON.

TO THE EDITOR OF THE "MECHANICS' MAGAZINE."

SIR,—The following very singular memorial of the celebrated Napier, of Merchiston, *inventor of the Logarithms* (may prove just now of service to the Emperor of China in any of his Quixotic plans), was presented to the War Office on the 7th of June,

A.D., 1596, is found in the 12th volume in the manuscript papers of Anthony Bacon, Esq., in the Lambeth Library, marked 658, anno 15996, Vol. V., which being unprinted, I send it *talis qualis*, to your useful magazine, as a curiosity.

I am, &c., J. B.

"*Secret inventions, profitable and necessary in these days for the defence of England, and withstanding of strangers, enemies to God's truth and religion.*

"First. The invention, proof, and perfect demonstration, geometrical, algebraical, of a burning mirror, which, receiving of dispersed beams of the sun, doth reflex the same beams altogether united, and concurring precisely in one mathematical point, in the which point, most necessarily it engendreth fire, with an evident demonstration of their error, who affirmeth this to be made a parabolic section. The use of this invention serveth for burning of the enemy's ships, at whatsoever appointed distance.

"Secondly, The invention and sure demonstration of another mirror, which, receiving the dispersed beams of any material fire or flame, yieldeth also the former effect, and serveth for the like use.

Thirdly, The invention and visible demonstration of a piece of artillery, which shot passeth not lineally through the army, destroying only those that stand in the random thereof, but superficially ranging abroad within the whole appointed place, till it hath executed its whole strength by destroying all those that be within the bounds of the said place. The use hereof not only serveth greatly against the army of the enemy on land, but also by sea, serving to cut down and destroy at one explosion the whole masts and tackling of so many ships as be within the appointed bounds, as well as abried as in large, so long as any strength at all remaineth.

Fourthly, The invention of a round chariot of metal, made of the proof of double musket, whose motion shall be such, that those that be within the same shall be more easy, more light, more speedy, and more safe in battle, than any hitherto contrived. The use hereof in moving is to break the array of the enemy's battle, and to make a passage, as also staying and abiding within the enemy's battle. It serveth to destroy the environed enemy, by continual charges and shot of the harquebuse, through small holes, the enemy in the meantime being abased, and altogether uncertain what defence or pursuit to use against a moving mouth of metal. These devices, besides inventions of sailing under water, with divers other devices and stratagems for harming of the enemies, by the grace of God, and work of expert craftsmen, I hope to perform.

(Signed) "JOHN NAPIER, of Merchiston,

"Anno Domini 1596, June 7th."

THE INSULATION OF THE PROPOSED PERSIAN GULF CABLE.

SIR,—It is very generally known that a long cable of some thousand miles or upwards is projected for the Persian Gulf. The matter has been decided on, and sample lengths for testing purposes have been sent to the Indian Board by different cable manufacturers. We may assume that a variety of methods of insulation are comprised therein, as well as the principal insulating agents—gutta percha and india rubber, also combinations of the two.

At this stage of affairs, therefore, and before any contract is entered into, it will not be irrelevant to take into consideration the subject, as to which material, and special application of such material to the conducting wire, would be most suitable for the proposed cables.

And first, as to gutta percha, which is, as we know, a good insulator, far better, in fact, than any of the compounds which have been invented as substitutes; but the difficulty is in getting it pure. And even supposing this overcome, we cannot be ignorant of the fact of the utter impossibility of insulating a wire therewith (to whatever thickness within reasonable limits) so as to have it as electrically perfect as circumstances require, it being, in reality, too much of a conductor to be an insulator of the first class. These considerations, of course, apply to all ordinary cases in which it is used, and where the temperature is too low to affect the gum. But this matter of temperature assumes paramount importance as applied to the use of gutta percha insulation for the tropics, and renders it wholly inadmissable, since, at a temperature of less than 80 deg., it becomes plastic and sticky; if, therefore, the conductor evinces a tendency to elbow its way through the insulation, the latter can offer no resistance in such a decomposed state. We have a lamentable and expensive illustration of this in the Rangoon cable, which could not withstand the temperature even of the ship's hold.

From a lengthened experience in India, devoted principally to telegraphic development there (in which it is but just to say he has been eminently successful, and earned the nation's gratitude), Sir W. Brooke had abundant proof of the total unfitness of gutta percha. Acting, therefore, upon the experience thus acquired, Sir W. Brooke, on his arrival from India, some twelve months' since, induced the Indian Board to order a caoutchouc core for the preliminary short cable of twenty miles, intended for some narrow part of the Persian Gulf; and the results of the testing of this cable demonstrate the wisdom of the choice, and that his successors, as telegraph engineers to the Indian Council, cannot possibly do better than tread in the footsteps of their predecessor in this respect. In fact, they must do so; the force of circumstances will compel them, unless, indeed, another series of gigantic failures is to be added to the disastrous shams which have already become a matter of history, certainly not to our credit as a nation of pains-taking and practical men.

At a temperature where gutta percha becomes a soft, resistless pulp, india-rubber retains its solidity intact, offering the test of guarantees for the cetricity of the conductor—a position of affairs, by the way, of the greatest moment to a submarine cable. It may, therefore, be unhesitatingly affirmed, that caoutchouc is the only material that can be successfully used as an insulator for cables intended for our Indian Empire, or any locality contiguous thereto.

A combination of the two gums, however, having been put prominently forward as being a far superior method of insulation than either percha or caoutchouc, singly, it becomes us to bestow some little consideration thereupon. The conductor, it appears, is to be first insulated with rubber to a certain thickness, because it is, perforce, the better insulator admitting of less induction; and then a series of coatings of percha, by way of protection, are to be added, to bring the core up to the required diameter; and the reason assigned for this singular species of manufacture is, that caoutchouc decomposes rapidly in sea water. Doubtless, in a long course of years, the action of sea water upon a cable would be to decompose the whole concern, however it might be constructed; but it is with reasonable periods we have to do, and certainly those persons who propose gutta pecha, or any other material as preventatives of the decay of caoutchouc, must adduce other and more cogent reasons than those which time and experience fail to verify. I can speak confidently, and from experience, when I assert that years of submersion in sea water, not only does not decompose rubber, but on the contrary hardens it, and improves the insulation. Sufficient consanguinity is not found to exist between the two gums to ensure that adhesive homogeneity in the entire core which is of such essential importance. It is evident, therefore, that this description of insulation will not do for the Persian Gulf cable, and is by no means to be recommended for any other, seeing also, that its electrical qualities will ever be far below the standard required.

To sum up, therefore, we want efficient telegraphic communication between every important part, near and remote, of our vast Indian Empire, and these again in immediate connection with the seat of Government at home; it is necessary, if this is done at all, that it should be done well, and as perfectly as the experience already acquired will admit of, and this points unmistakeably to caoutchouc as the prime insulating agent for this purpose. PHILO.

OBSERVATIONS ON THE SHOEBURYNESS EXPERIMENTS WITH WHITWORTH'S SHELLS.

SIR,—In my last letter containing some remarks on "Civilian's" communications, I was led to observe that if iron armour on our vessels was of sufficient thickness to keep out shells, that would be the limit of utility, and that wood would better provide for what further defence might be deemed requisite; but really it would seem by last week's experiments that we are to be deprived even of this immunity, in regard at least to any thickness of plates which sea-going ships could carry. I confess that this result surprises me in regard to shells, although capped with steel, but not so in regard to shot; for I anticipated the great superiority of steel for projectiles in your number for December, 1858, when I made these remarks:—"That the species and phenomena of force cannot be limited to what is observable of momentum alone: that a blow, to be viewed practically, must be seen in two aspects, as the result of, and measurable by, momentum, and as the result of and measurable by *vis viva*: that it is in the latter aspect crushing effects must be contemplated: that it will depend on *practical circumstances*, such as the comparative *hardness* of the conflicting materials, on the velocity being the prominent factor in the *vis viva* of the shot, and on the particular angle at which it strikes, whether it shall freely glance from, crushingly graze, or more crushingly lodge in, or penetrate through, the iron casing of a ship: and that the great enemy these ships will have to contend with is, the rifled cannon with *steel* shot."

All these observations have a bearing on the recent experiments, but I can refer now to only two. It will be observed that I make the penetrative efficiency of shot to depend, not merely on comparative hardness, but on the prominency of the factor velocity, (equal amounts of *vis viva* being understood), that is to say, while I acknowledge with Sir William Armstrong that the real power of shot is proportional to the mass and the square of the velocity, I do not believe that, *cæteris paribus*, penetrative effects are proportional thereto at very high velocities, but that resistance decreases in the case of some materials and some forms of the action in an unknown ratio with the time permitting resistance. There are many phenomena which, to my mind, are inexplicable, except on such an hypothesis, and these Shoeburyness experiments confirm me in the idea. I do not believe that the real law of resistauce against penetration is known, although the mathematical conception of it may approximate nearly to it within the range of moderate velocities. There may not be much deviation in the case of wood within these limits, and possibly not within any practical velocities (which would be a valuable property to ascertain); but I strongly suspect the mathematical law in the case of iron, especially when a hole made in it is the result of a piece being driven out. We know that the resistance which is so exceedingly regular in the compression of gases within a certain range, and even beyond it to some extent, if we allow time to operate, becomes very irregular as we approach the limit of liquefaction, and similar irregularities may belong to the disparting as to the compression of the molecular forces.

Now this hypothesis furnishes me with this corollary in regard to the matter in hand, that we could pierce armour plates equally well with wrought or cast iron, as with steel projectiles, if we only had the means to give them that high degree of velocity at which the resistance against separation in the plate is less than against compression in the shot. As the effect depends on velocity as well as on the comparative hardness of materials, it will stand in relation to both, leading thus to changes variable, and sometimes paradoxical, according to ordinary apprehension. Thus, a candle, with the velocity for the case, will perforate a board; and an electric spark will punch a minute hole through two inches of solid glass—a proportion of depth to diameter somewhat exceeding the law laid down by "Civilian" for punching processes. It seems to me very probable, that velocities exist in relation to certain materials, in respect to which the suddenness of impact is such as to render null, practically speaking, all cohesive resistance; and where the only resistance encountered is that due to the inertia of the parts carried away. Is not this so, when a bullet cuts out a clear round hole in a pane of glass? And did not Mr. Whitworth's hexagonal shells make an hexagonal hole? the surrounding, parts, as I understand it, remaining intact. No doubt this sudden palsy, as it were, with which molecular forces are struck, is explainable on mechanical principles, but what I am now concerned about is simply the fact. With a penetrating force, increasing *cæteris paribus* with the square of the velocity, and a resisting force, decreasing in some manner with the velocity, we can well conceive that we may have arrived at a point where the efficiency of plate armour is diminishing at a very rapid ratio; and that no very great advance on the present velocities may be needed to render iron casing useless within any reasonable thickness. But on the same hypothesis, on the other hand, the tenacity of the material for cannon, under the condition of great velocities being generated, would also be rapidly approaching the limit of safety; and, in truth, the frequency of their bursting on any mode of construction—although fired with much less charges than formerly obtained, and simply because the obstruction produced by rifling has been the means of eliciting a larger proportion than heretofore of the potential force existing in gunpowder—is a circumstance that goes far to confirm my hypothesis.

It is possible, therefore, that we have already got very near to the length of our tether, both for offence and defence.

I think that the flat ends of Mr. Whitworth's shells have little to do with the perforating effect. Flat ends produce more immediately the shearing strain to cut a piece out of the plate, but the round end will do the same, by quickly and virtually forming for itself a flat end out of the plate. This, at least, is always the case when a piece is punched out, and a round shot will do that when the plate is thick, and is struck with great velocity. The effectiveness of Mr. Whitworth's projectiles appears to me to be due, partly to the superior velocity arising out of his admirable method of rifling, and partly to the greater cohesion of his material—steel—by which all the work, virtual in that velocity, is done wholly on the plate, and not at all on the projectile itself. When a shot is shattered into fragments, there is a partial reversal of the action, and a waste, more or less, or, it may be, entirely, of all our efforts as to one mode of destructiveness. It is true the power of the projectile is wholly expended on the plate, in the effect, momentum; but if the plate is not indented, it is also wholly expended on the shot, in the effect, work; the manner thereof being a crushing of the missile. Nor is this a paradox; for these effects, though they both occur, and both flow from the same more remote cause, are not cumulative in relation thereto, but successive by successive origination. But if the plate is indented, then the work done is between the shot and plate. Now, the effect, momentum, we care nothing about, except for the crash that may possibly be the result; but the effect, work, is sought te be wholly done on the plate; and steel projectiles give us the means of thus wholly utilising the power which has been so long in our hands without turning it properly to account. Hitherto we have been losing projectile efficiency, by allowing the shot to absorb so large a portion of it. Perhaps, in some of the testing trials, the shot should have come in for praise or blame, instead of the plates. Four years have nearly passed away since the use of steel for shot was recommended in your pages.

But what is to be done now in the way of defence? I scarcely know how to give even a tolerable answer to this question; and begin to fancy that now I am indeed in the position "Civilian" assigns to me, of a maladroit doctor called into a consultation, who, scorning a *placebo*, replies to his *confreres* about the man dying, if nothing is done for him, that it is a truism, and that his own truism is, "all men are mortal." However, here is my nostrum. We must make our armour plates of steel, and with just that proportion of carbon which gives the greatest toughness and hardness without brittleness, so as to offer the best security against a piece being punched out of the plate, and to insure a strain, circumjacently and extensively, upon the contiguous parts. We must get far away from the glass type of resistance. We must thoroughly anneal the steel, but carefully avoid any great heat in this process, so as not to undo the toughness which the previous manipulations had imparted to the metal. The pinch of the rollers must be enormous, especially for thick plates, so that the compression may be felt to the core, otherwise internal strains will exist. Or the plates must be hammered with hammers of great weight and little velocity; we must have the metal in that state, if possible, that when pierced, it shall bulge and open with a burr without loss of substance, even under the greatest velocity that we can get guns to impart to shot. To this end also, and to extend the area of the strain, we must allow the plates to bend to the blow, as much as is compatible with the security of the fastenings (if fastenings cannot be dispensed with), and not back them up with a network of stiff iron framing, which would only facilitate the punching process, after the manner of dies, for all the interspaces. By-the-bye, this snapping of the fastening bolts, presents another illustration of my hypothesis. Now the elasticity of wood backing allows this moderate bending of the plates in a very convenient manner. Having placed steel plates upon a layer of wood, we must next add, over all, a casing of bronze, that is, of gun-metal plates, the edges of which must be fused together, in the manner of making junctions of the parts of a bronze statue. In this way we cut the knot of the difficulty about plate fastenings, for there need not of necessity be any. The great danger the "Warrior" will run, will be to have her plates knocked off by a pounding of heavy shot. My idea as to the further advantage of a bronze casing, is this, that the shot, impinging first on the gun-metal, would have its velocity so reduced, as to nullify the danger of a punching action, peculiar to impact with high velocities on the harder steel plates; and that it would be forced to do its work against a lacerating, disparting kind of resistance, to which the strength of surrounding parts would be rendered tributary. I repeat this idea, because I would not be understood to say that otherwise, that is in the case of uniform resistance, it would make any difference whether the one or the other metal was pierced first. There is another circumstance to be noticed in favour of this double casing; a flat-headed, tempered steel shot, would carry before it a flat plate of gun-metal, a little larger, perhaps, than itself, and compress it against the steel plate, and thus the advantage of superior hardness in the shot would be nullified by the intervening softer metal, which would have to be crushed in a confined chamber, as it were, until it was wholly squeezed out of the way, before the harder metals could come into contact. I think that here the round-headed shot would have the advantage; but with respect to either, the retardation would be immense. It would be the same case, virtually, as that of the work done, and lost in the crushing of the shot. I do not recommend steel plates in order to countervail tempered steel shot, for that would be a vain expectation, but to inflict such crushing work upon all other kinds of shot, and to condense into the same weight of plates a greater power of resistance than what resides in iron. Steel plates under this arrangement, need not be large, and would not, therefore, be much more expensive than the present immense iron plates, taking weight for weight; and probably they would be less costly for equal resistances. The proportions for the defence might be these:—gun-metal, 2½ in., steel, 3½ in., wood, 18 in., ship's skin, 0. As I must not now encroach further upon your space, I shall only observe, that the expansion of the gun-metal casing with heat has not escaped my notice.

Bnt it will be said that the expense would be enormous, because of the high value of gun-metal. Yes; war is a costly game to play at, and such it always ought to be. Money is a precious commodity; but life, the life of a nation, is infinitely more more precious.

Yours, &c.,

Nov. 17. BENJ. CHEVERTON.

P.S. There were some typographical errors in my last communication, the principal of which were these:—"Destruction," for obstruction; "*repousse* worked," for *repousse* work; and "6," for 9.

Meetings for the Week.

MONDAY.—SOCIETY OF ENGINEERS.—"On the Inundation of Marsh Land," by B. Latham, Esq., at 7 p.m.
LONDON INSTITUTE.—"On the Class Reptilia," by R. Owen, Esq., at 7 p.m.
TUESDAY.—INSTITUTE CIVIL ENGINEERS.—"On some of the Internal Disturbing Forces of Locomotive Engines," by Mr. A. W. Makinson, at 8 p.m.
WEDNESDAY.—LONDON INSTITUTE.—"On the Operation of Heat," by E. W. Brayley, Esq., at 7 p.m.
SOCIETY OF ARTS.—"On Thompson's Process of Boat Building by Machinery," by D. Puseley, Esq., illustrated by models, at 8 p.m.
FRIDAY.—LONDON INSTITUTE.—"On the Chemistry of the Non-Metallic Elements," by F. Field, Esq., F.R.S.E., at 7 p.m.

Gossip.

In our volume for 1859, page 43, there is an interesting account, by Mr. D. J. Fitzgerald, on the application of the hygroscopic properties of chloride of calcium to the drying of buildings, linen, tobacco, &c. In the western annex of the International Exhibition, we noticed that the surfaces of Krupp's samples of steel, broken by the hammer, and kept under glass cases, were in a singularly bright and untarnished state. On examination we found that this was owing to the presence of chloride of calcium; a saucer containing some of this deliquescent salt being placed in every glass case.

Maizena, or corn flour, has become an article of food of importance. The flour is made from the white or pearl corn of the middle states of America, and is manufactured by the Glen Cove Company, of New York. It has been introduced into this country by Mr. W. J. Townsend, and at the Exhibition it received a medal. The corn from which maizena is manufactured is raised in a climate where the summers are long, and of a temperature that ripens the grain to a state of perfection not attainable in colder or warmer countries.

The stage machinery of the new Vienna Opera-house is to be worked by a steam engine of eight-horse power.

A distinguished physician in Paris, Dr. Robert De Lambelle, announces that a shock of electricity given a patient dying from the effects of chloroform, immediately counteracts its influence and restores the sufferer to life.

An extraordinary meeting of the shareholders of the Atlantic Telegraph Company, will be held at the London Tavern, on Friday, the 12th of Dec., for the purpose of considering a proposition for the issue of £600,000 new capital in preferential shares of £5 each.

Mr. Gisborne, late commissioner for Newfoundland in the International Exhibition, has patented an invention of a system of ship's steering signals, and has received instructions from the Board of Admiralty to fit the apparatus in her Majesty's ship "Rhadamanthus," at Woolwhich. The apparatus consists of a couple of boxes, placed respectively on the bridge and in front of the helmsman, which are connected by means of a strong electric cable. On the face of each box are four metal flaps, under which are painted the words "port," "starboard," &c. These are worked by the simple touch of a knob or handle attached to the box, and the orders are replied to in a similar manner, without the slightest risk or danger of the order being misunderstood as at present, by means of the voice.

The *Saturday Review*, which is notorious for its universal genius in sneering at all animate beings and inanimate things, save and except Dr. Pusey and wax candles, has been guilty of some very amusing blunders, in treating on a subject of guns. Amongst other absurd assertions, it states, in an article entitled "Whitworth *v.* Armstrong," (a notice, by-the-by, in which both plaintiff and defendant are addressed in a very "Lord Chief Justice" sort of tone), that Sir William Armstrong has adopted and perfected the plan of building his guns of coiled metal forged into a solid mass. Mr. Whitworth professes to obtain greater strength by using a mass of homogeneous iron bound round with hoops of the same material. The confused ignorance displayed in these assertions, coupled with the arrogant line of the whole article, form a very *piquant* combination.

THE SMITHFIELD CLUB CATTLE SHOW.—On the 8th of next month, and the four following days, this show will be held at the new Agricultural Hall, at Islington. The building is, as yet, not quite completed. We understand that the *Building News* will give a full illustrated description of it next week. The building is 76 ft. high, and its galleries are 36 ft. wide. The heavy machinery will be placed under the galleries; the live stock in the open space of the main hall, the lighter exhibits being placed in the galleries. The award of prizes and private view will take place on Saturday the 6th, and the club dinner will take place on the 10th of December.

THE COLOUR OF SHIPS.—The deep black, says an American paper, which our ships have been painted, has proved to be a very prominent mark to shoot at, in consequence of which a change has been made to a greyish drab. The steamers "R. R. Cuyler" and "Ossipee," now at the Portsmouth Navy Yard, have been painted this shade, which makes them much more "invisible," so that one standing on one side of the river can hardly distinguish the vessels from the wharf or the water, whereas a small black boat and a schooner stood out in bold relief.

VENTILATING FANS.—Mr. Atkinson stated, at the last meeting of the Northern Institute of Mining Engineers, that within the last few days he had been trying some experiments with a fan of similar construction at Tursdale Colliery, near Durham, and gave some of the results arrived at. Mr. Atkinson also gave some account and description of the fan used by the Pneumatic Despatch Company in London, by which 14 inches of water pressure could be obtained. The principle appeared to him to be capable of being applied to the ventilation off mines with advantage. The fan consisted of two discs, and was about 20 feet in diameter, and made above 200 revolutions per minute. It was constructed so as to allow of this velocity being obtained, whilst the Elsecar fan could not with safety be driven above 70 revolutions per minute. By the Pneumatic Company's fan he obtained 30,000 cubic feet per minute through an opening of six square feet. The President stated that at first the company had considered it necessary to have the piston in the tube quite tight; they now, however, found that this was not necessary, and that little loss was caused by a space being left all round the piston. This materially reduced the friction.

Patents for Inventions.

ABRIDGED SPECIFICATIONS OF PATENTS.

THE Abridged Specifications of Patents given below are classified, according to the subjects to which the respective inventions refer, in the following Table. By the system of classification adopted, the numerical and chronological order of the specifications is preserved, and combined with all the advantages of a division into classes. It should be understood that these abridgements are prepared exclusively for this Magazine from official copies supplied by the Government, and are therefore the property of the Proprietors of this Magazine. Other Papers are hereby warned not to produce them without an acknowledgement :—

STEAM ENGINES, &c., 1257, 1318.
BOILERS AND FURNACES, 1312.
ROADS AND VEHICLES, including railway plant and carriages, saddlery and harness, &c., 1277, 1300, 1307, 1313.
SHIPS AND BOATS, including their fittings, 1243, 1272, 1273, 1301.
CULTIVATION OF THE SOIL, including agricultural implements and machines, 1258, 1262, 1302.
FOOD AND BEVERAGES, including apparatus for preparing food for men and animals, 1242, 1252, 1253, 1263, 1275, 1291, 1295.
FIBROUS FABRICS, including machinery for treating fibres, pulp, paper, &c., 1247, 1261, 1265, 1270, 1280, 1286. 1287, 1292, 1293, 1317, 1321, 1323.
BUILDINGS AND BUILDING MATERIALS, 1251, 1278, 1322.
LIGHTING, HEATING, AND VENTILATING, 1254, 1271, 1282, 1285.
FURNITURE AND APPAREL, including household utensils, time-keepers, jewellery, musical instruments, &c., 1245, 1264, 1274, 1276, 1283, 1297, 1298, 1305, 1308, 1325.
METALS, including apparatus for their manufacture, 1260, 1269, 1294, 1314.
CHEMISTRY AND PHOTOGRAPHY, 1244, 1267.
ELECTRICAL APPARATUS, 1255, 1268, 1304.
WARFARE, 1266, 1281, 1290, 1303, 1319.
LETTER-PRESS PRINTING, *none*.
MISCELLANEOUS, 1240, 1241, 1246, 1248, 1249, 1250, 1259, 1279, 1284, 1288, 1289, 1296, 1299, 1306, 1309, 1310, 1311, 1315, 1316, 1320, 1324.

1240. G. B. GOODMAN. *Apparatus for preventing accidents in or at mine shafts.* Dated April 28, 1862.

This invention consists in an arrangement of machinery or apparatus which suspends the mine skip, or cage, if, by the breaking of the chain or otherwise, the said skip or cage becomes detached from the winding apparatus. *Patent abandoned.*

1241. J. BURNIE. *Improvements in tobacco pipes.* Dated April 28, 1862.

Under one modification the stem of the pipe, which may be formed of metal, wood, glass, or other suitable material, forms a moderately wide tube or cylindrical chamber. The lower part of this chamber has fitted to it, or is formed with, an internal tube, which extends a short distance up the pipe stem. The diameter of this internal tube corresponds to and is intended to receive the tube of the bowl, which is preferred to be made short. An ordinary mouthpiece is fitted into the upper end of the stem, and this is preferred to be made so that its tubular extremity extends a short distance down the stem. The bowl of the pipe is fitted with an internal moveable disc; this consists of a small perforated metal plate fitting the lower part of the bowl, and extending over the aperture through which the smoke is drawn. The disc is formed with a thin slip of metal, which is bent upwards and bent over the edge of the bowl to admit of its being lifted out, bringing with it the contents of the pipe. With these arrangements the tube of the bowl cannot get stopped by the ashes of the tobacco, whilst the only matters drawn out of the tobacco in smoking condense in the inner surface of the stem, and flow down into the space round the inner tube, which effectually prevents the return of the fluid to the bowl. *Patent abandoned.*

1242. J. FLETCHER. *Treating saccharine liquids.* Dated April 28, 1862.

The first part of this invention has for its object the superseding the use of open fire-heated boilers employed for boiling saccharine liquids, and consists in the arrangement and employment of an evaporating apparatus to perform the operation with greater advantage. The second part of the invention consists in an improved construction of apparatus for evaporating liquids, whether treated in the ordinary fire-heated boilers, or in the improved apparatus described for superseding the same. The third part of the invention consists in the construction of an improved cooling or granulating apparatus, in which the molasses of the sugar formed by the cooling of the liquid, treated in the preceding apparatus, is run off before the sugar is packed for transport. The fourth part of the invention consists in the construction of an apparatus, of comparatively small cost, in which the clarifying, evaporating, and granulating operations necessary for the manufacture of sugar from cane juice may be successively performed at option. *Patent abandoned.*

1243. R. VAILE. *Improvements in propellers for ships.* Dated April 28, 1862.

This invention relates to endless chain propellers, and consists in means for maintaining the floats attached to the chains in proper positions, and for driving the chains. The chains are passed round two or more drums or rollers. The drums are furnished with projecting rims or collars, having indentations to receive the chains; the drums may be placed either in a horizontal, vertical, or angular position. The floats are cut so as to receive the drum collars, and attached to the chains a little above, below, or in the centre. The floats work in grooved guides, and are furnished with projecting arms and friction rollers. They are feathered and prevented from getting into a wrong position by the action of the water, and by their arms coming in contact with guides. The upper part of the propeller works in a curve, and provision is made for hoisting the whole apparatus on deck in case of need. *Patent completed.*

1244. W. T. GLIDDON. *A new and useful mode of restoring phosphatic guano.* (A communication). Dated April 29, 1862.

The object of this invention is to resuscitate and restore phosphatic guanos to their original quality and effectiveness, and this is accomplished by reimpregnating them with such ammoniacal and alkaline salts as are a material aid in the luxuriant growth of the herbaceous part of the plants, and rendering a part of the basic phosphates soluble by converting them in one and the same process into bi-phosphates or super-phosphates. The reagents which have been selected for the above purpose are, first, all kinds of nitrogenous matter, such as carrion, of any description, fish, blood, or offal from slaughtered animals; in a word, any or all kinds of nitrogenous matter yielding ammonia may be employed. Secondly, Acids, preferring sulphuric acid. Thirdly, The fixed alkalies, such as soda and potash for instance. Fourthly, Sulphate of lime, or sulphates whose bases have less affinity for their acid than the nascent ammonia. *Patent completed.*

1245. G. R. SAMPSON. *Improvements in valves or cylinders for wind musical instruments.* Dated April 29, 1862.

This invention consists in a new and improved system of pistons or valves out of, and forming a portion of, the main and added tubing of each instrument, and is measured and calculated as a portion of the sounding part of the same. In this system of pistons or valves the air enters into them vertically at the top or bottom, or horizontally, in the middle, on one side of the piston, only coming out at the top or bottom, but never going through them from one side to the other, as in ordinary systems. The air passes through one of the pistons at all times, whether it is pressed down by means of a rod or not, and when the same is pressed down, it brings the added tubing into use; then the air passes through both ends of the pistons. *Patent completed.*

1246. H. F. WELLS. *Improvements in screw clamps or cramps for joiners and other work.* Dated April 29, 1862.

This invention consists in the use of a notched or plain bar of metal of any desired length, according to the purpose to which the cramp is to be applied, with one or more sliding arms formed in the manner described. When one arm only is used, the end of the bar is turned up to form an abutment or pressing surface, against which one side of the material to be clamped, cramped, or compressed, is placed. The sliding arm is self-fixing by its peculiar form, and when placed in the proper position upon the bar forms the other abutment. An adjusting screw, fitted either in the head of the bar, or in the end of the sliding arm, or in both, completes the cramp. In place of twining one end of the bar up, a plain bar, notched in opposite directions, and two sliding arms, may be added. The sliding arms are formed with a hole or slot at one end, through which the bar can be passed. The arms can thus be moved along the bar to any required position. *Patent completed.*

1247. J. W. and F. G. OALEY. *An improved textile fabric.* Dated April 29, 1862.

This invention, although more especially intended for window roller blinds, may be applied to other uses. The blind is of cotton, and manufactured with a semi-transparent pattern, that is to say, with figures or designs in gauze or open work, very similar to lace or net. Through this gauze or open work light penetrates more fully than through the ground or close part of the fabric, which, when used for a blind, has a very rich appearance, and which, while softening the light, diffuses more within the apartment than the ordinary even or patternless blind. The improved fabric is produced by the gauze or open works part having the threads in the warp twisted together according to the requirement of the pattern to be produced, and the plain or ground part of the threads in the warp rising and falling two threads up and one thread down alternately. *Patent completed.*

1248. J. E. A. GWYNNE. *Improvements in machinery for lifting, forcing, and exhausting, and in the application of the same.* Dated April 29, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1249. R. E. DIXON. *A smoker's pipe and tobacco pouch.* Dated April 29, 1862.

The distinguishing nature and character of this invention consists in arranging and fitting a small compact box or case for holding and protecting the pipe when not being used, and for keeping and carrying matches and other little articles of convenience for smokers, and in connecting and combining therewith a bag or pouch for keeping the tobacco for smoking, which, however, is entirely distinct from the pipe case, except when the pipe is to be filled, when communication is made between the two without opening or detaching either, and the pipe filled without the use of the hands or fingers to put the tobacco in the pipe. *Patent abandoned.*

1250. S. W. NEWINGTON. *Improvements in apparatus for letting off and stopping the flow of liquids from casks and vessels, such apparatus forming a tap, and substitute for the ordinary vent peg.* Dated April 29, 1862.

This invention consists in forming a tap and substitute for the ordinary vent peg, by having an ordinary tube or duct with an open or perforated end, to be inserted into the cask or other vessel of capacity. and also provided with a nozzle or outlet (though it is not a matter of necessity, as in ordinary taps, that the same should be provided with a stopper, neither does the patentee ordinarily use the same). The nozzle is provided with a flexible tube, which has a small tube at its end, whereby the liquid can be let off when required, or the flow thereof stopped, by simply inserting the same in the vent hole of barrel, cask, or vessel of capacity, thus stopping the vent hole and the flow of liquid by one and the same operation. Hence, by this arrangement, when letting off is in progress the vent hole is unstopped, and when the letting off is finished, the vent hole is to be stopped by the said tube. *Patent completed.*

1251. E. CLARK. *Improvements in arches.* (A communication.) Dated April 29, 1862.

This consists in the peculiar arrangement and construction of arches for bridges, roofs, and similar structures, more particularly when the openings to be arched are of considerable space. These arches are composed of bars, or plates, arranged in the form of a single or double series of triangles. *Patent completed.*

1252. W. CLARK. *Improvements in preserving animal and vegetable substances.* (A communication.) Dated April 29, 1862.

This relates to improvements in the preservation of all kinds of animal and vegetable substances, by the use of steam, or other method of producing a vacuum, whether the alimentary substances be used as human food or used for feeding animals. The methods of operation are of two kinds, according as the animal or vegetable substances are preserved, without being previously dried for that purpose. In order to preserve alimentary substances in their natural state, without being previously dessicated, the patentee uses air-tight reservoirs, surrounded on the exterior with impervious materials, such as india-rubber, gutta-percha, or other substances. These reservoirs are provided with doors, opening easily, and luted, so as to be perfectly air-tight when closed. Grapes, plums, pears, nuts, or eggs, may be preserved without providing a vacuum, it being only necessary to completely fill the reservoir, care being taken to fill the interstices with powdered charcoal, coke, schistons, or bituminous blak, or tissue paper. *Patent completed.*

1253. J. ROSS. *Improvements in grinding stones or surfaces for grinding grain and other substances.* (A communication.) Dated April 29, 1862.

This relates to conical grinding stones, which the patentee forms of pieces of stone, placed in a conical cast-iron shell, in which they are rigidly fixed. By this means a hollow conical grinding surface is cheaply and easily made, which is as efficient for the purposes of grinding as if made in one piece. He fixes the iron shell, with its stone lining, in suitable framework, as the bed or stationary stone of the mill, and mounts the solid conical running stone on a shaft, by which it is driven. *Patent completed.*

1254. R. BRIGHT. *Improvements in lamps and in apparatuses for lighting Argund and other wicked lamps.* Dated April 29, 1862.

This invention consists in employing in oil lamps a "bob" at the end of a cord, string. or wire, to indicate the perpindicularity or level. The invention also consists in admitting air into the reservoir in oil lamps through a bent tube in the face or fore-part of the lamp reservoir, whereby the lamp may be carried at various inclinations without spilling the oil. The apparatuses for lighting lamps consist of a lamp with two wick holders at such distance apart that they will embrace, or contain between them, the Argand or other circular wick, or the two ends of a straight wick, to be lighted, and in such manner as to light the wick on opposite sides or ends at the same time. *Patent abondoned.*

1255. J. CLIFF. *Improvements in insulators for supporting telegraph wires.* Dated April 29, 1862.

This invention consists in constructing what the inventor terms a compound insulator, as hereafter described :— The compound insulator consists of two parts; the outer part is formed with a notch in the top for the reception of the telegraph wire; the other part consists of a shaft carrying near the bottom thereof a disc, the diameter of which is nearly equal to that of the inside of the mouth of the outer part; the bottom of the shaft has a hole formed in it for the reception of the pin, or stud, by which it is connected to a post or other support. The head of the shaft is intended to be lodged in a recess formed in the inner and lower part of the body of the outer part, in order that the two parts may be united to form the compound insulator by means of sulphur or other suitable insulating cement. Care must be taken that the shaft and upper part shall in no part be in contact, therefore the size of the recess must be large compared with the size of the head of the shaft. In order to prevent wet or moisture injuriously affecting the insulator, he applies a coating of shellac into the upper angle or head inside the outer part. The recess into which the head of the shaft is inserted is enlarged at the bottom, and for further security against damp or wet affecting the insulator, the inner surface of this bottom part may be coated with shellac, or the space between it and the spindle may be filled with that material. *Patent abandoned.*

1256. W. L. TIZARD. *Improvements in heating, cooling, and condensing apparatuses.* Dated April 29, 1862.

This invention was described and illustrated at page 330 of the present volume of this journal. *Patent completed.*

1257. D. M. CHILDS. *Improvements in steam engines.* (A communication.) Dated April 29, 1862.

This relates to the steam chest and valves. The steam passes through a pipe and enters a steam space which surrounds the valve; the port being in communication with a branch passage, conducts the steam to the cylinder port, and, acting upon the inner head of the piston, forces the same forward, and by causing the fly-wheel to revolve, operates the connecting-rod, which is attached to the valve-lever. The exhaust escapes through the cylinder port, the passage, and escape pipe, which are thus brought in connection, and the valve-lever being operated by the connecting-rod, causes one-fourth turn or revolution of the valve, and brings the ports in connection with the branch passage, and thereby opens the exhaust; the supply port being in communication with the passage, admits the steam through the passage and cylinder port to the outer surface of the piston head. The patentee uses the throttle of a double-acting engine to reverse the engine. *Patent completed.*

1258. D. M. CHILDS. *Improvements in reaping and mowing machines.* (A communication.) Dated April 29, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1259. D. M. CHILDS. *Improvements in the means of changing a rotary into a reciprocating, and a reciprocating*

into a rotary movement in machinery. (A communication.) Dated April 29, 1862.

In carrying out this invention there is a slot in the device or frame as long as the stroke or motion required, and through which the shaft is designed to travel or pass, and there are grooves crossing the centre of the slot at right angles with the same. The groove is designed to receive a slide which operates upon a crank wrist. *Patent completed.*

1260. E. B. WILSON. *An improvement in the machinery or apparatus used in the manufacture of malleable iron and steel.* Dated April 29, 1862.

This consists in placing the tuyere or tuyers of the converting vessel (which is suspended on axles) above the molten vessel, and in blowing down upon or through the metal, in place of blowing up through the same as heretofore. *Patent completed.*

1261. W. E. NEWTON. *Improvements in machinery for picking, burring, and cleaning wool and other fibrous substances.* (A communication.) Dated April 29, 1862.

We cannot here give space to the details of this invention. *Patent completed.*

1262. W. E. NEWTON. *Improvements in the construction of mowing and reaping machines.* (A communication.) Dated April 29, 1862.

The patentee claims enclosing the whole or portion of the driving parts of reaping or mowing machines in a case or box, as described, for protecting such parts from injury from the weather or from other causes, and the mode shown and described of carrying forward the stalks of cut corn, so as to form a continuous swath when they have been cut. *Patent completed.*

1263. M. HENRY. *Improvements in apparatus for ærating liquids, and in fastenings for the said apparatus, and for other articles.* (A communication.) Dated April 29, 1862.

Here the mount or cover of the vessel is placed on a ring or collar, formed or fixed on the neck of the vessel, and has hinged or jointed to it two bent, curved, or arched arms, links, or pieces, to which are hinged or jointed other arms, which may be described as levers, and which, when depressed, are brought into such position that portions of them are caused to bear against or take into the under surface of the ring or collar, by which the mount is securely fastened on the vessel; it is disengaged therefrom by raising the jointed arms and thereby moving them from or causidg them to clear the ring or collar. The inventor employs a tube, divided so as to form two distinct passages, or fluid ways, one of which is for admitting liquid to the powders in order to generate the gas, and the other is for the exit of the ærated liquid from the apparatus. The apparatus for the æration of liquids consists of two chambers or compartments, one (the upper) for containing the liquid, and the lower for holding the powders; and the tube is applied to this apparatus so that the inlet way shall lead at bottom into the lower or powder chamber, and shall open at top into the upper or liquid chamber, at a height regulated according to the quantity of liquid required to be injected on the powders for generating the gas. *Patent completed.*

1264. E. MOORE, *Improvements in the manufacture of dress shirts and dresses.* Dated April 30, 1862.

Here, instead of using materials of the ordinary texile nature, consisting of weft and woof, the patentee makes or weaves the dress shirts and dresses, manufactured in accordance with this invention, entirely with a continuous thread in stocking frames by the process known as framework knitting, so that they shall possess the qualities and advantages of that manufacture, especially its elasticity, in every direction of the fabric, and its consequent durability. The articles are woven in the frame in parts from a cut pattern, such parts being combined in the frame by the process known to framework knitters as "hanging on" or "picking on," and the articles being then completed by weaving on in the ordinary way practised in the manufacture of articles of hosiery. *Patent completed.*

1265. A. TRAVIS and B. TRAVIS. *Improvements in engines for carding cotton and other fibrous materials.* Dated April 30, 1862.

This consists in an eccentric or crank pin fixed in or formed upon a pulley, which is free to rotate upon a stud fixed in a bracket from the framing of the engine. This pulley is driven by a belt or band from the axis of the main end cylinder, or any other convenient rotating part of the engine. The eccentric or crank is arranged to work in a space formed lengthwise in an arm or lever secured to the end of the shaft passing in front of the doffer, which shaft carries the doffer comb. The stud upon which the pulley eccentric or crank is placed is adjustable, so that it can be brought nearer to or further from the comb shaft, and thus two oscillating movements, produced by the rotation of the eccentric or crank, can be made of greater or less extent, as required. *Patent completed.*

1266. A. J. MAHON. *Improvements in projectiles.* Dated April 30, 1862.

This improved projectile is in the form of a bolt, and may be of any suitable shape at the front end, either conical, hemispherical, or otherwise, but the rear or cylindrical portion of the projectile is grooved, rifled, or cut in planes at any desired angle internally, externally, or both, and provided or not with apertures round the cylindrical band under the solid front of the propeller, or along the grooves, so that the gas generated by the explosion of the charge may be forced through the apertures, and impart a twist or spinning motion to the projectile in the barrel, such projectile scarcely touching the sides of the same. *Patent abandoned.*

1267. J. HARRINGTON and T. PERKINS. *An improvement or improvements in mounting photographic portraits for visiting cards, and in mounting photographs in general.* Dated April 30, 1862.

This consists in making a depression in that part of the card at which the photograph is to be mounted, the said depression being of the size and shape of the photograph, and constituting a sunk recess in which the photograph is placed and secured by gelatine or other adhesive material. *Patent abandoned.*

1268. G. DAVIES. *An electric apparatus applicable to various useful purposes.* (A communication.) Dated April 30, 1862.

This consists in the application of electric apparatus or gearing to various useful purposes. 1. To the working of breaks, signals, and other apparatus on railways. 2. To feeding steam boilers, and to water-gauges, pressure-gauges, and safety-valves. 3. To regulating the temperature of gas, and of hot or cold air and fluids in general. These results are obtained by the action of an electric pile, with optional intermittent contact, acting either manually or automatically upon appropriate gearing or apparatus. *Patent completed.*

1269. G. DAVIES. *Improvements in the manufacture of nails, screws, and other analogous articles in malleable cast iron.* (A communication.) Dated April 30, 1862.

The patentee claims the substitution of malleable cast iron for wrought iron in the manufacture of nails for stove making and other purposes, and of various small articles of ironmongery, which may be either covered with a coating of another metal or not, as described. *Patent completed.*

1270. A. T. MERCIER. *Improvements in weaving looms.* Dated April 30, 1862.

These improvements apply principally to the following parts:—1. The lifting of the boxes by the cording or tie-up, by squares communicating by metal rods with other squares which lift the shuttle boxes. 2. Metal racks, the teeth or notches of which uphold the boxes at their different heights by cramps or pawls in connection with the carding. 3. Notches, flats, or plates pressed by a spring against the two fingers or branches of a lever tied to the cordage by a cord, which, raising the lever, cause the pawl to leave the notch of the rack, and permits the box to change its position. 4. A rack provided with two fingers, which, finding themselves placed before one or other driver, permits one or other of the shuttles to throw according to the requirements of the design to be produced. This rack is set in motion right or left by a pinion which toothes into it, and fixed on a shaft, at the end of which is also fixed a crescent, the two ends of which are fastened by cord to the lifting wires of the cordage. *Patent abandoned.*

1271. J. MAIDEN. *Improvements in safety lamps.* Dated April 30, 1862.

This consists in adapting to the ordinary Davy lamp certain springs, catches, and other contrivances, whereby the lamp is rendered both self-locking and self-extinguishing. *Patent completed.*

1272. E. LEIGH. *Improvements in the construction of ships and floating batteries, in mounting their guns, and in the application of steam power, part of which improvements are also applicable to land batteries and forts.* Dated April 30, 1862.

Here the inventor makes the paddle-wheel propellers work between pontoons astern, the propeller being made with shrouds and buckets similar to a water-wheel, the buckets being air tight, or partially so, the edge of each float being set a little zigzag. When they enter the water the air within them is compressed, and serves to keep the water towards the periphery of the floats; as the floats leave the water the air rushes out, and pushes the water away from them, the recoil acting in the direction of propulsion. In other respects the paddles are detached and acted upon, and acted upon for steering purposes if required. For destroying an enemy's ship the inventor arranges a cylinder and piston (upon the principle of the steam hammer), whereby a prodigious blow can be delivered. In mounting ships' guns he balances two guns at the end of a lever, which works on a pivot. The said guns, when at rest, are below the port-holes, and lie in a horizontal position. *Patent abandoned.*

1273. T. PIATTI. *Improvements in the propulsion of ships and other vessels, and in the means and apparatus employed for this purpose.* Dated April 30, 1862.

Here propellers are mounted upon the ends of the main driving axis, or shaft, on each side of the vessel, like the ordinary paddle-wheels, and the apparatus consists of two wheels, circles, or frames, which are keyed or fixed at a suitable distance apart upon the main axis near the sides of the vessel. These wheels, or circles, are connected together by studs, or bolts, and are formed with three arms or projections, through which other studs, or bolts, are passed, and upon which the propeller blades, or oars, are mounted, serving as axes upon which they can swing or move freely. The axis on which each propeller blade, oar, or paddle is mounted (and upon which it is capable of making a partial revolution), is placed near its centre; and as the end of each paddle enters and passes through the water to propel the vessel, the opposite end is borne against one of the studs, or bolts, which connect the two circles, or frames, together. Near the outer extremity of each blade, or paddle, friction rollers are carried, which enter into or between circular grooves, or guides, fixed on the sides of the vessel, and fixed in a position eccentric to the main driving axis, so as to govern the relative positions of the propeller blades during their revolution. *Patent abandoned.*

1274. H. HICKMAN. *The more securely fastening of ladies' crinoline skirts and other articles of wearing apparel, and also for the fastening of elastic and other bands.* Dated April 30, 1862.

This consists in the use of a perforated piece of metal, made in such shape or form as is required in the making of ladies' crinoline and other skirts, dresses, and articles of wearing apparel; also for the more securely fastening elastic and other bands. Being perforated, the piece of metal becomes, when applied to tapes, wires, or other substances, immovable, consequently more durable than any now in use. *Patent abandoned.*

1275. J. OXLEY. *Improvements in apparatus for cutting and chopping bread and other substances.* Dated April 30, 1862.

This consists, essentially, in the use of a knife which is connected at each end to a lever, vibrating on a centre, on the table or base of the apparatus, so as to impart a draw cut to the knife. *Patent completed.*

1276. G. H. BIRKBECK. *Improvements in the construction of couches or settees for the purpose of sitting, lying, or reclining upon.* (A communication.) Dated April 30, 1862.

Here the permanent seat of the couch or settee consists of an elastic surface, formed by springs, or stuffed with elastic materials, and beneath this surface a drawer or receptacle is formed, which is carried by the framework (mounted on castors), which supports and forms the couch or settee. To one side of the bottom or supporting frame another frame is joined or hinged, so as to form, when raised and fixed in an inclined position, an elastic surface or back to the couch, to rest or recline against. The front of this hinged frame has a loose or elastic cloth or cover attached thereto, and is stuffed with suitable soft or elastic material to form the bed when the frame is moved down into a horizontal position, so as to rest and be supported upon the spring or elastic surface of the couch or settee. There are other details. *Patent abandoned.*

1277.—J. M. CARTER. *Improvements in harness and the shafts of carriages.* Dated April 30, 1862.

This invention is not described apart from the drawings. The patentee claims, 1, the attachment of the ends or points of the shafts to the frame or other receptacle fastened on to the collar or other breast part, as also the method set forth for regulating the length of the shaft. 2. Dividing a portion of the shaft lengthways, and having an opening in the same for admitting the tug. 3. The attachment of the surcingale to the under part of the tug. If a bar within the terrett with an opening, or a terrett which has an opening, and the height of the interior of which, or that part intended for the reins, is less than the width of the reins. 4. A receptacle for that portion of the shaft straps, which support the traces in double harness, which is surplus caused by the action of the horse. *Patent completed.*

1278. A. PRINCE. *A new composition for casting to represent marble.* (A communication.) Dated April 30, 1862.

The patentee claims the composition formed of minerals and waterglass, or silicate of soda, or potash, or both, substantially in the manner specified, constituting a substitute for gypsum and marble, for the purpose of casting copies of figures, busts, relievos, and articles of sculpture of every kind, &c. *Patent completed.*

1279. W. STAUFEN. *A new material to be used in the manufacture of brushes, and also applicable to the purposes for which bristles, horsehair, and human hair, are now used.* Dated April 30, 1862.

Here the patentee takes the fibres of the tree known to botanists as the *Arenga Saccharifera*, and treats them with a hot alkaline solution, in order to remove the resinous matter, after which the fibres are dyed, dried, and sorted into suitable lengths and thicknesses. *Patent completed.*

1280. J. L. NORTON. *Improvements in apparatus for drying fibrous materials and yarns.* Dated April 30, 1862.

Here the patentee uses a drum, which, at its periphery, has fixed to it or receives a number of cases or boxes, arranged in a circle or polygon around the drum. The boxes or cases are each perforated at the top and bottom, and within the circle enclosed by them there is a fan, which is caused to rotate rapidly and produce a current of air through the boxes; the drum, with its boxes, also rotate, but at a comparatively low speed, so as to turn over the fabrics or yarns, and keep them in motion, so that the current of air may act on every part. *Patent completed.*

1281. J. M. NAPIER. *Improvements in machinery for manufacturing projectiles.* Dated April 30, 1862.

Here the patentee, in the compressing machine, uses a first or weighing die, which partially forms the blank after it is cut from the lead rod, and, at the same time, the surplus lead is forced through an aperture in the die, and is cut away, so that the exact quantity of lead required to fit the second or finishing die is left, and when the finishing impression is given, there is no surplus lead to be detached from the bullet. *Patent completed.*

1282. A. H. FIELDEN. *Improvements in show jars, lamps, signals, and light-houses, and other methods of illumination to be called the "rainbow light."* Dated April 30, 1862.

This consists in the introduction into show glasses, of glass rods or tubes, bent or straight, either white or coloured, so disposed as to allow of the tubes being illuminated. The same principal the patentee adopts in signals, lamps, light-houses, &c. *Patent completed.*

1283. H. F. BROADWOOD. *Improvements in the construction of pianofortes.* Dated April 30, 1862.

This invention is not described apart from the drawings. The patentee claims, 1. The invention of screwed wrest-pins into plated wrest-planks, in the manner and for the purpose described. 2. Forming metallic pin plates of a bent or compressed shape as described. 3. The mode described of fixing and retaining wooden pin plugs in their places by compressing the plugs before driving, and by forming notches or irregularities in the holes. *Patent completed.*

1284. H. WILLIS. *Improvements in valves for the supply and discharge of gaseous bodies.* Dated April 30, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1285. W. E. NEWTON. *Improvements in lamps.* (A communication.) Dated April 30, 1862.

This relates to a mode of securing the chimney to the cone, and of securing the cone to the burner, whereby the chimney is allowed to expand as it heats, and is thereby prevented from breaking. The invention also admits of the cone being firmly secured to the burner, and serving as a handle, to allow of the chimney and cone being removed from the burner while hot, so that the wick tube may be exposed, and the wick trimmed easily at any time. *Patent completed.*

1286. W. T. LOY. *Improved machinery or apparatus for carding cotton and other fibrous substances of a similar character.* (A communication.) Dated April 30, 1862.

This consists in altering the position of the "workers" and "strippers," whereby the patentee is enabled to purify the cotton in a complete, easy, and economical manner. *Patent completed.*

1287. J. Swallow and J. Allinson. *Improvements in the manufacture of carpet fabric.* Dated May 1, 1862.

This relates to the production of a novel description of carpet fabric, obtained by peculiar weaving of the character of tweeled venetian, in which the warp threads are brought to the surface in pattern without break of tweel. *Patent completed.*

1288. W. B. Smith and W. Bennetts. *Improvements in the method of and apparatus for preventing the injurious effects occasioned by smoke, sulphur, and the deleterious gases which escape from stacks, chimneys, calcining houses, chemical and other furnaces.* Dated May 1, 1862.

Here the flue, which is conducted from the back of the fire, must be carried on to a small case, in which is a blast fan, from whence the flue must be continued to a chamber, or, if need be, to a succession of chambers. When the blast fan is made to revolve rapidly, it causes a draft in the flue, which can be regulated as desired, and which carries onward the smoke and the gases evolved during combustion, and the air which passes into the fire and discharges when into a chamber or a succession of chambers, where they are treated according to their nature, no air being allowed to escape but that which is harmless, and this is passed through a finely perforated metallic plate, or through a sheet of canvas, which is affixed to the outlet from the chamber into which they are discharged. *Patent abandoned.*

1289. C. P. A. Douchain. *Improvements in apparatus for letting in or shutting off water or other liquids.* Dated May 1. 1862.

This consists in the construction of a sump cock, which may be visited and repaired without removal from the conduit or pipe to which it is fitted. For this purpose, the cast-iron sump, which is conical, carries two hollow dovetailed fillets, in each of which dovetail a leather washer or guage corresponding with the cock, and fixed simply by the dilitation of the leather, which is placed on its thickness when wet, a little ammonia being added when necessary to fix the oxydation. This leather, thus held on the sump, rubs against two surfaces, in brass or bronze, of a cone forming one body with the cast-iron cock, having previously been turned with it, and imprisoned by a hydraulic press and conical mandril. Thus the cock is of one piece, which lessens the chance of leakage; and in case of accident to the leather washers, they may be rapidly replaced by taking the upper part of the cock to pieces, lifting out the sump, cutting the old washers into two or three pieces to permit their withdrawal, and substituting new ones, which are all turned of the same calibre or guage. This arrangement is also applicable to all kinds of cocks. *Patent completed.*

1290. T. Holmes. *An improvement in the manufacture of military cartouches, port-monaies, courier bags, letter bags, knapsacks, and other articles of a like nature.* Dated May 1, 1862.

This consists in the insertion of a steel wire spring at the bottom of the cartouch, port-monaie, courier bag, &c., with arms extending up the back and front of the cartouch, port-monaie, &c., which act so as to insure the perfect satety of the contents of the several articles above named. *Patent abandoned.*

1291. W. Huntington and T. Huntington. *Improvements in the machinery for the manufacture of bread.* Dated May 2, 1862.

Here, the yeast and other required materials are put into long narrow troughs, which troughs are placed one at a time on a platform, which has imparted to it a reciprocating motion below a pair of rotating transverse shafts which project over the edge of the shaft at each side. The shafts are fitted with specially constructed arms or heads for kneading the dough, and when in motion, the shafts revolve in opposite directions. A large hopper is provided (above the frame) and arranged to supply the flour gradually and regularly. There are other details for manipulating the dough, in order to form it into loaves. *Patent completed.*

1292. H. Kohn. *Making any kind of stuffs, textures, or fabrics waterproof.* Dated May 2, 1862.

This waterproofing composition is composed of 1-16th of an ounce of bone flour, the white of an egg, 1-16th of an ounce of salt alkali, and dissolves the whole in a quart of pure water. *Patent abandoned.*

1293. W. Bodden and W. Mercer. *Improvements in certain parts of machinery for slubbing and roving cotton and other fibrous substances.* Dated May 2, 1862.

This relates to slubbing and roving frames, and consists in certain modes of connecting the pressers to the legs of the flyers, by which the slubbings and rovings are wound on the bobbins. *Patent completed.*

1294. T. F. Griffiths. *An improvement or improvements in raising or shaping sheet iron.* Dated May 2, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1295. R. Walker. *Improvements in malting, and in apparatus therefor.* Dated May 2, 1862.

This improved apparatus consists of a cylindrical vessel divided into separate compartments, and formed with sides made of a permeable material. An external, close, or impermeable casing may be provided, to be applied or removed as required. The cylindrical vessel is mounted so that it can be turned by gearing, and so that the motion imparted can be varied or modified in any desirable way. Provision is made for applying heat to the vessel, either directly or by means of heated air, for example; and for this purpose the vessel may be enclosed in a chamber, so that the air current or the amount and proportions of other gases (which it is in contemplation in some cases to apply) may be easily regulated and controlled. In the case of several vessels being employed, the process may be arranged so as to be at different stages in different vessels, or in different sets of vessels at the same time, whereby considerable economy will be obtained. *Patent completed.*

1296. O. C. Evans. *A reversible attachment to a shaft or arbor for converting reciprocating rectilinear into rotary motion.* Dated May 2, 1862.

We cannot here give space to the voluminous details of this invention. *Patent abandoned.*

1297. O. C. Evans. *An abdominal truss intended for the more perfect support and cure of hernia.* Dated May 2, 1862.

This invention consists in making the truss with six instead of one or two pads, as in most instances of this class, two hernia, two iliac, and two lumbar. The hernial pads are connected one with the other by (what the inventor here terms) a pubic bar, which is a steel or iron bar extending from the one to the other, and which is made in two separate pieces, and united by a set screw in a manner so as to form a slide joint. And this in order to enable the wearer as well as operator to adjust the pads at will to the width of the pelvis and position of the hernial ring or rings. *Patent abandoned.*

1298. C. Ashwell. *An improved safety fastening, applicable to the locks of doors.* Dated May 2, 1862.

This invention consists in a piece of mechanism of the following construction:—In the middle of the length of a piece of wood, or other material, a slot is formed, about an inch in length, in which is fitted a sliding hook, the lower end of which protrudes through the said slot, and is fitted with a thumb screw; another hook is screwed into the solid part of the wood, near to one end of the aforesaid slot, the bows of said hooks being placed in opposite directions, thus,)(; on one and the same side of the piece of wood a hole is formed crosswise through each end of the aforesaid piece of wood, in which a ring is placed, each ring having a long cord fastened thereto. To use this improved safety fastening the moveable hook is slackened, and the points of the two hooks passed through the bow of the key in the lock of the door, the key being inserted in that side of the lock which is in the room; and, supposing it to be a bedroom, the occupant, on retiring to rest, having first locked the door, he inserts the hooks of the fastening in the bow of the key, and, pushing the sliding hook outwards to its full extent, screws it tightly in that position, and proceeds to place the strings aforesaid behind the pillow of his bed, or in any other place within his reach when in bed. By pulling one string the key will be turned partly round and the door unlocked, and by pulling the other string the door may be locked without the person having to get out of bed for that purpose. *Patent abandoned.*

1299. R. A. Brooman. *Improvements in apparatuses for superheating steam.* (A communication.) Dated May 2, 1862.

This invention consists in the use of cast iron hollow rings, by preference three, each divided into four equal segments; the rings are of different diameters, and are arranged stepwise one above the other, and at such distances apart as will allow the products of combustion free circulation. Connection is maintained between the rings by bent tubes. The first of these hollow rings is of the same internal diameter as the flue in which the superheater is placed. When the superheater is fitted to a marine engine, steam enters directly from the boilers, and passes to the cylinders. Valves for cutting off, and admitting the steam, are fitted so as to enable the steam to pass directly from the boilers to the cylinders in the ordinary manner, without passing through the superheator, and also to enable part of the steam only to pass through the superheater and be afterwards mixed as before. Each tube is free to expand and contract independently of the others, and has only to bear its own pressure and that on the ring. This result is obtained by the tubes being bent, which renders them slightly elastic, and allows them to play without injuriously affecting their joints *Patent completed.*

1300. C. F. Whitworth. *Improvements in apparatus for signalling upon railways,* Dated May 2, 1862.

The objects of this invention are to provide against any liability to collisions, especially where there are steep gradients, curved cuttings or tunnels, and other obscure places. To provide a warning of the approach of trains to stations, crossings, opening bridges, and other places. To afford means of ascertaining at any time whether a distant signal is on or off, although from some local obstruction, fog, storm, or other casualty, the signal itself may be invisible. The peculiar merits of this invention are, that all that the proposed advantages are obtained by combined means, so arranged, that very little power and momentum are required to ensure efficient action, and the concussion of impact, even at the highest velocity of trains, is so slight as to preclude all liability to fracture or derangement in action. The invention consists in certain arrangements of apparatuses (which cannot be described without reference to the drawings) which, by the aid of electro-magnetism, work signals upon railways. *Patent completed.*

1301. M. Paul. *Improvements in windlasses and capstans or ships rounding apparatus.* Dated May 2, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1302. J. W. Gill. *Improved apparatus for turning up and pulverizing the soil of land for cultivation.* Dated May 2, 1862.

This invention consists, principally, of a cylinder with plates, lines, or other suitable implements projecting therefrom, which cylinder is connected to a traction engine, and is thereby drawn slowly over the land, at the same time that it is caused to revolve rapidly on a horizontal axis, by means of hands or suitable gearing driven by the engine, and thus to turn up and pulverize the soil. *Patent abandoned.*

1303. H. Welch. *Improvements in securing or attaching armour plates on or to ships or vessels.* Dated May 2, 1862.

In carrying out this invention, the hull or shell of the ship or vessel is constructed of iron, and the side plates or skin of the vessel at that part which is intended to be protected by armour, is constructed in such a manner that spaces are left between the plates which form the shell. The edges of these plates are bevelled inwards, so as to form a kind of dovetail joint. A dovetail groove, corresponding to that in the shell of the vessel, is planed out of the back of the armour plate, so that when the latter is bent to the proper curve, and is brought to its place on the ship's side, the two dovetails will be coincident. An alloy of copper in a molten state, and somewhat resembling gun metal, is then poured into the double dovetail groove, and will firmly hold the armour plate on the ship's side. In order to secure two contiguous plates together by their edges, dovetail grooves are planed out of the edges of the contiguous plates, and when the two plates are brought together, the double groove is filled up with the molten copper alloy, and thus a secure joint is produced. *Patent abandoned.*

1304. A. V. Newton. *Improved electrical apparatus applicable to the lighting of gas.* (A communication.) Dated May 2, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1305. W. Mossman. *Improvements in the manufacture of bonnets, hats, or coverings for the head.* Dated May 2, 1862.

This invention consists in the application of enamel cloth to the manufacture of bonnets, hats, or coverings; such cloth may be of any woven fabric, spread over with any pigment such as is used in the manufacture of enamelled or satin surfaced cloths, paper, cardboard, or pasteboard, and of any colour. The application of this enamelled cloth, or satin surfaced cloths, to the manufacture of bonnets may be either in pieces, shapes, or lengths to imitate straw, chip, crinoline, leghorn, willow, and the like. *Patent abandoned.*

1306. J. Brierley. *Improvements in the construction of fire-plugs, or valves, to be used in extinguishing fires, or other purposes where water is required to be drawn from mains under pressure.* Dated May 3, 1862.

The object of this invention is to construct fire-plugs, or valves, in such a manner that the flow of water from the main is unimpeded by any of the working parts of the valve, and, by thus reducing the friction, to secure the greatest amount of effective force. *Patent abandoned.*

1307. H. Juhel. *Improvements in wheels.* (A communication.) Dated May 3, 1862.

This invention consists in substituting for the ordinary flat band an elbowed-concave band of iron, steel, or any other metal, for wheels of every description of carriages. To this effect, the patentee makes the felly so shaped that it may receive the elbowed-concave metallic band, which clamps to the upper part of the said felly, to which it adheres, without having recourse to the heating of the said metallic band, thus avoiding the cineration or carbonization of the wood, and the subsequent inconvenience that arise from the said cineration or carbonization. This cold process, besides, allows the use of steel for bands, which has been hitherto rejected for this manufacture, as it loses, by the heating process, its primitive and peculiar properties. *Patent completed.*

1308. J. Tyler. *Improvements in the manufacture of clarionets.* Dated May 3, 1862.

Hitherto in clarionets the C sharp in the third space, and the F sharp on the third ledger line below, have been produced by a closed key on the left side of the instrument when held to the mouth. According to these improvements, the patentee changes the key which produces these notes from the left side to the right side, and makes it an open key, which is closed by the fourth finger of the right hand. In the ordinary clarionet, on the right side there is an open key, from which the notes D natural, on the fourth line, and G natural, under the second ledger line below, issue. The head, or finger end, of the lever of the latter key he places under the head or finger end of the new C sharp key. He presses down both by the fourth finger of the right hand when required. A projection or lever from the long lever B natural key acts upon the D key. On the long lever B natural key being pressed down by the fourth finger of the left hand, the D key is closed, the new key stands open, and produces the notes C sharp in the third space, and F sharp in the third ledger line below. *Patent completed.*

1309. E. Omerod and C. Schiele. *Improvements in machinery or apparatus for cutting or dressing stones, which are also applicable for hammering, crushing, or otherwise reducing metals and other materials.* Dated May 3, 1862.

This invention relates, principally, to improvements on a patent granted to Christian Schiele, dated the 22nd day of February, 1860 (No. 475), and it consists in causing the swinging tools to strike at an angle before arriving at the lowest point of motion, and in guiding them past or over the block of stone to be cut or dressed, preventing any subsequent contact. The patentees also guide them in their course during the swinging out, by centrifugal force, and control their position when striking the material, as well as regulating the depth of the cut or other action, and the subsequent rebound, without interferring with any earlier accidental strokes. *Patent completed.*

1310. H. G. Moffatt. *An improved advertising medium.* Dated May 3, 1862.

This invention consists in the employment of the wrappers of note paper for advertising purposes. Instead of merely ornamenting them and designating their contents, as at present adopted, the inventor prints or ornaments them with any desired number of designs, and of various colours, arranged so as to include a number of advertisements in suitable positions, or a separate advertisement in each design or compartment. The object is to have as many advertisements on one wrapper as may be required for utility and ornament. *Patent abandoned.*

1311. J. M. Herdevin and J. A. Julliens. *Improvements in sluice cocks.* Dated May 3, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1312. T. Snowdon. *Improvements in the manufacture of steel tyres, hoops, and cylinders, and in furnaces employed therein, and applicable to the melting of steel generally.* (A communication). Dated May 3, 1862.

This invention consists in manufacturing steel tyres, hoops, and cylinders, in angular crucibles or melting pots, and in constructing the furnaces with two or more fireplaces or gas generators, the flames or heated gases from which are caused to impinge and circulate both round the exterior and through the hollow space or interior of the crucible or melting pot, When employing the furnace for

other than angular melting pots, several separate pots or crucibles, of any ordinary form, may be arranged in one, two, or more tiers round a common centre, so as to leave a central hollow space for the reception and passage of the flame or gases. *Patent completed.*

1313. J. H. HEPPEL. *Improvements in the construction of permanent way of railways.* Dated May 3, 1862.

One part of these improvements relates to that description of permanent way where double-headed rails and the ordinary chair are employed. The inventor constructs longitudinal sleepers, either of wrought iron or puddled steel, the transverse section of which is formed of a trough shape, with a flange on either side of the trough. These longitudinal sleepers are placed opposite each other on the road, each opposite pair being connected together and kept to gauge by means of wrought iron tie bars or rods. Upon the before-mentioned longitudinal sleepers he fixes the ordinary cast iron chairs carrying the rails. These chairs are placed transversely across the sleeper, so as to rest upon each flange of the same, to which they are attached by means of pins or bolts passing through, and secured either by others, or by screwed nuts, or by riveting at the underside of the flanges. *Patent abandoned.*

1314. J. HERDMAN. *Improvements in the manufacture of wrought iron, steel, or combined wrought iron and steel plates, adapted for ship building and other purposes for which strength and lightness are required.* Dated May 3, 1862.

These improvements have reference more particularly to an invention for "Improvements in the manufacture of wrought iron plates adapted for ship building and other purposes for which strength and lightness are required," for which letters patent were granted to John Herdman, bearing date the 12th of May, 1855 (No. 1,071). In the specification of the aforesaid invention were described various arrangements for forming cellular or hollow plates of wrought iron, by welding together two or more plates having ribs or bosses upon their inner surfaces. Now, one part of the present improvements consists in forming such plates of wrought or cast steel, instead of wrought iron, or partially of wrought or cast steel and partially of wrought iron. Another part of the present improvement consists in forming one wrought iron or steel plate with ribs, bosses, or projections, and the other with grooves or recesses of a slight depth, so that when the two plates are being welded together, the ribs, or projections on the one plate enter into the grooves or recesses on the other plate, by which a more perfect union of the two plates will be effected; or, in some cases, such cellular plates may be formed by welding together a corrugated plate of iron or steel, and a flat plate placed on either side of the same, the inner surfaces of such flat plates being, by preference, somewhat grooved for those portions of the corrugated plate that come in contact with them to fit into, so as to insure a more perfect weld. Another part of this invention consists in forming such cellular plates by placing two or more flat iron or steel plates, having small projections or ribs on their faces, opposite each other, a certain distance apart, so that a space is formed between each two plates, into which space are placed suitably-formed cores, and cast-steel, in a molten state, is then poured into the remaining interstices, which, when solidified, will be firmly attached to the plates by the before-mentioned projections upon the latter being fixed in the cast-steel. The cellular plates thus formed may then be heated to a welding heat, and the parts of the same be welded together more firmly, either by hammering or by rolling. *Patent completed.*

1315. W. BLACK. *Improvements in lottery and ballot-boxes.* Dated May 3, 1862.

We cannot here give space to the details of this invention. *Patent abandoned.*

1316. G. VEAL. *Improved apparatus for obtaining and applying motive power.* Dated May 3, 1862.

Here the inventor proposes to use a very long and powerful helical steel spring wound up in a barrel, and attached by suitable gearing, to a driving wheel, either for the purpose of working machinery, or more especially for propelling carriages on common roads. The spring will, by its length and power, exercise its influence for a lengthened period, and when exhausted, or nearly so, it may be removed, whereby in a small compass a motive power may be obtained and applied to various useful purposes. *Patent abandoned.*

1317. M. HENRY. *Improvements in the process of and apparatus for preparing materials for the manufacture of paper, and in obtaining products from agents used in the same process, part of the invention being also applicable to apparatus for washing.* (A communication.) Dated May 3, 1862.

According to these improvements the materials are disposed in or separated into thin layers, or strata, which are divided or separated from each other, and in that divided or separated condition undergo the boiling, heating, steaming, alkaline treatment, washing, or other disintegrating or preparing process or processes. Moreover, while the process is being carried on, the materials should be kept from contact with the sides of the boiler, receiver, or holder containing them. They may also be separated, stirred, or moved about during the treatment. *Patent abandoned.*

1318. J. FOWLER. *Improvements in engines for hauling agricultural implements.* Dated May 3, 1862.

According to this invention, the patentee so constructs the engine that it may be used either for ordinary tilling or for drain ploughing. This he does by mounting underneath the boiler of the engine, and between the fore and hind wheels, two drums mounted on vertical axes, and so drawn that one makes several revolution for each revolution of the other, the two axes being geared the one to the other by spur wheels properly proportioned. The fast running drum he prefers to have nipping instruments upon it, so that it may hold a hauling rope which passes only half round it. The slow running drum he prefers to be a winding drum to wind or coil up the rope upon itself, but it may be a nipping drum very strongly made. In place of mounting both the fast and the slow drums, so that they both remain permanently on the engine, he sometimes so arranges the apparatus that the fast running drum may be removed, and a slow running drum, with its intermediate gear, substituted therefor, the frame of the engine being accurately fitted and prepared to receive such parts. *Patent completed.*

1319. E. MEROLLA. *Improvements in firearms.* Dated May 3, 1862.

This invention consists in the employment of a cover to the nipple, which, when the piece is put at half-cock, can be brought over the nipple and cap thereon, so as to protect the cap from blows arising from the accidental descent of the hammer or otherwise, and likewise to protect it from rain and moisture. *Patent completed.*

1320. W. E. NEWTON. *An improved method of joining boxes.* (A communication.) Dated May 3, 1862.

This invention has for its object to join the ends of boxes in a more perfect, neat, and efficient manner than can be done with nails or glue, or by dovetailing the ends. The invention consists in the employment of strips of metal bent into an angular form, and inserted endwise into the slots cut in the bevelled ends of the box stuff, by sawing or otherwise, so that these strips, when inserted, will bind and secure the corners tightly together. *Patent completed.*

1321. J. MELLODEW and T. MELLODEW and C. W. KESSELMEYER. *Improvements in looms for weaving.* Dated May 3, 1862.

This invention refers to a method of making the shed in looms, and consists in interrupting the motion communicated by the motive power to a roller or other apparatus, so that it may be caused to deviate from its course in the one direction or the other, and so impart an upward or downward motion to the picks or heddles. *Patent completed.*

1322. C. SCHLICKEYSEN. *Improvements in machinery for moulding bricks, tiles, pipes, and turf.* Dated May 3, 1862.

This invention is not described apart from the drawings *Patent completed.*

1323. J. HEYWORTH. *Improvements in looms for weaving.* Dated May 3, 1862.

This invention consists in causing the continued motion of the loom to be dependent upon the shuttle having struck the check "strap" or straps. For this purpose, the patentee connects the check strap to an arm capable of being moved out of the way of the "frog" when the said strap is struck by the shuttle, but should the shuttle become "trapped," then the check strap, not being acted upon, allows the said arm to remain in a line with the "frog," so that the motion of the loom is arrested. *Patent completed.*

1324. P. V. LEFEBVRE. *A self-feeding pen-inkstand.* Dated May 3, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1325. A. WILLIAMS. *The construction of a backed form or seat capable of being converted into a level table with seat, or a desk, either level or sloping, or at any angle.* Dated May 5, 1862.

This invention consists of an iron standard consisting of two uprights, connected at the top and bottom by horizontal iron plates, at the upper front corner of which a tenon is inserted and secured by a pivot in the mortice of the other portion of the standard, to which is attached the board to form the back of the seat. Down upon the horizontal plates before mentioned, another board is secured, and forms the seat itself. By raising the back board before mentioned, and turning it forward upon the joint formed by the mortice and tenon before referred to, the back board of the seat forms a level table; or, by being secured by a screw through the cheek of the mortice to be turned forward against the tenon, the back board will be held in any sloping position required, and will form a writing desk. *Patent completed.*

PROVISIONAL PROTECTIONS.

Dated July 14, 1862.

2026. O. P. Drake, Massachusetts, America. A new and useful or improved apparatus for vapourizing and aërating a liquid hydro-carbon to be burned for illumination, or for other purposes.

Dated September 22, 1862.

2588. J. Long, Gorleston, Great Yarmouth. An improved machine for cleansing and scraping streets, roads, or ways.

Dated October 21, 1862.

2840. C. Trees, Blackfriars-road, and F. C. Belhomme, New-street, Covent-garden. Improvements in hats, caps, bonnets, and other coverings for the head.

Dated October 23, 1862.

2853. A. Chaplin and G. Russell, Glasgow, engineers. Improvements in obtaining fresh water by evaporation, and in apparatus therefor.

2857. M. C. A. Perkes, Belvedere-house, Rosendale, Dulwich, spinster. An equilibrium double-action revolving rudder, self-balancing drag, and improved steering gear. (A communication.)

2859. H. Donald, Johnstone, Renfrew, engineer. Improvements in machinery or apparatus for bending or straightening metal plates.

2861. J. Field, Lambeth, engineer. Improvements in steam engines, condensers, and boilers.

Dated October 24, 1862.

2863. A. J. F. V. Brepson, 30, Boulevard de Beaumarchais, Paris, architect. A siphoidal cistern, with water reservoir, for kitchen or other drains in communication with infected sewers.

2865. L. Groux, Victoria Soap Works, Woodhouse Junction, near Sheffield. Improvements in the manufacture of soap, and in machinery for that purpose.

2867. J. R. Nicholl, Streatham, Surrey, clerk. An improved construction of fireplace or stove grate.

2870. P. S. Devlan, Buckingham-street, Strand, engineer. Improvements in the manufacture of bearings, steps, axle-boxes, and other surfaces and appliances or articles subjected to friction.

Dated October 25, 1862.

2873. W. Owen, Rotherham, engineer. Improvements in stoves.

2875. D. Brown, Smethwick, and W. Brown, Smethwick, gun barrel manufacturers and iron masters. Improvements in rolling machinery for rolling gun barrels, cannons, and other articles.

2877. W. Clark, 53, Chancery-lane. An improvement in the construction of the joints of cast iron gas and water mains and other pipes. (A communication.)

2879. P. Alfraise, 51, Rue de Malte, Paris. Improvements in sewing machines.

2880. T. G. Ghislin, Hatton-garden, importer. Improvements in the treatment and utilization of certain foreign plants for the obtaining of useful fibres therefrom.

2881. E. A. L. Negretti and J. W. Zambra, Hatton-garden, meteorological instrument makers. Improved apparatus for ascertaining or testing the explosibility of liquid hydro-carbons. (A communication.)

Dated October 27, 1862.

2883. J. Chattwood, Bury, architect. Improvements in ventilating rooms and cellars.

2885. J. H. Johnson, 47, Lincoln's-inn-fields, gentleman. Improvements in heating glass furnaces. (A communication.)

2887. F. Lipscombe, 233, Strand, water filter manufacturer. Improvements in purifying water.

2891. J. J. Ridge, Thomas-street, St. John's, Southwark. Improvements in treating certain farinaceous substances applicable to infants' or invalids' food, and in apparatus to be employed therein.

2895. T. Richardson, Newcastle-upon-Tyne, chemist. Improvements in the manufacture of sulphate of soda.

Dated October 28, 1862.

2897. J. Chalmers, 8, Knight's-place, Wandsworth-road. Improvements in armour plating ships of war and fortifications.

2901. H. Allen, St. James-place, St. James-street, engineer. Improved apparatus for preparing leaves and stalks of plants for being cleaned or dressed for the purpose of obtaining the useful fibres they contain.

2903. E. S. Tudor, Upper Thames-street, white lead manufacturer. Improvements in the purification of lead.

2905. J. Jeffreys, The Rise, Hoddesdon, Herts. Improvements in constructing surface condensers and apparatus for heating and cooling fluids.

Dated October 29, 1862.

2907. A. Ripley, Brook-street, West-square, engineer. Improvements in the construction of pistons for steam engines, which improvements are also applicable to air and liquid pumps.

2903. A. Shanks and F. Kohn, engineers, 6, Robert-street, Adelphi. Improvements in hydrostatic presses.

2909. G. Darlington, Minera, Denbigh, zinc smelter. Improvements in the manufacture of zinc oxide.

2911. A. Hogg, Londonderry, shirt manufacturer. Improvements in smoothing irons.

2913. W. Clark, 53, Chancery-lane, engineer. Improvements in the treatment of copper ores, and in apparatus for the same. (A communication.)

2914. I. W. Lister, J. Bottomley, and W. Bottomley, Well-oth-lane, Rochdale, tool makers. Improvements in looms for weaving.

2915. W. Cook, 26, Spring-gardens, civil engineer. Improvements in apparatus for ventilating.

2917. W. E. Gedge, 11, Wellington-street, Strand. Improved apparatus in connection with the pans of water-closets. (A communication.)

2919. D. Fryer, Carlton-square, Old Kent-road, and J. W. Meears, Annett's-crescent, Islington. Improvements in casks, tanks, or other receptacles for containing petroleum and other oils or spirits.

2921. J. Unsworth, Rochdale-road, Manchester, engineer. Improvements in steam engines.

2923. H. P. F. Newham, St. Mary's-gate, Nottingham, lace manufacturer. Improvements in the manufacture or production of reversible shawls.

2924. J. Fletcher, sen., Leeds, and J. Fletcher, jun., Newcastle-on-Tyne. Improvements in forming wrought iron wheels, and in the tools and apparatus for making the same.

Dated October 30, 1862.

2925. J. Lockwood, Batley, York, rag merchant. Improvements in boilers.

2927. F. Gregory, Manchester, Lancaster, agricultural machinist. Improvements in presses for pressing seeds, fruits, hops, and other substances.

2929. J. Eaton, King's Norton, Worcester, chandelier maker. An improvement or improvements in the manufacture of certain kinds of gas burners for illuminating purposes.

2931. P. Giffard, 66, Boulevard des Batignoles, Paris, civil engineer. Improvements in air guns and other arms.

2933. J. Birch, New Norfolk-street, bricklayer. Improved apparatus for unstopping or clearing from obstructions drains, water closets, stack, water, and other pipes.

Dated October 31, 1862.

2937. W. R. Bowditch, clerk of St. Andrews, Wakefield. Improvements in carburetting or napthalizing gas, and in the apparatus employed therein.

2938. H. L. Corlett, Inchicore, Associate of the Institution of Civil Engineers. Improvements in the construction of tuyeres.

2939. G. Dickinson, Smethwick, manufacturer, and E. Cook, Smethwick, manager of works. Improvements in the construction and ornamentation of metallic bedsteads, couches, and children's cots.

2941. A. Andrews, Birmingham, mechanic. An improved tool for cutting and rasping pegs in boots and shoes.

2943. G. H. Morgan, Hereford. Improved mechanical arrangements for raising and lowering bodies.

2945. M. C. de C. Sinibaldi, 1, South-villas, South-street, Greenwich. Improvements in the manufacture of armour plates for ships, fortifications, and forts, and in the manufacture of plates to be used in the construction and building of ships, and for attaching copper, or other like protective metal to the outside of metal plates, for making copper bottoms, or bottoms with a similar protection, to iron ships, and for other purposes.

2949. W. E. Newton, 66, Chancery-lane, civil engineer. Improvements applicable to the carriages and beds of guns, mortars, and other ordnance. (A communication.)

2951. J. G. Marshall, Leeds, flax spinner. Improvements in the treatment of the straw of flax, hemp, and other similar vegetable substances preparatory to spinning the fibre thereof.

2953. J. J. Anderson, St. James-street, Northampton, currier. A new or improved mode and means for the production of leather from waste leather scraps, and also for producing from such waste leather scraps, in combination with india rubber, gutta percha, or other like substance, a new material to be used as leather, and for other purposes.

Dated November 1, 1862.

2955. J. W. Taylor, Newsome, near Huddersfield, manufacturer. Improvements in scouring or cleansing woollen, worstead and cotton fabrics, and other fibrous materials, and in the means or apparatus employed therein.

2961. J. Winter, Wardour-street, Soho. An improved safety tap or cock, applicable to gas burners, gas pipes, and vessels containing gas; also water pipes, steam pipes, and vessels containing inflammable and other liquids, compressed air, and spirituous liquors.

Dated November 3, 1862.

2963. J. Musgrave, Globe Iron Works, Bolton-le-Moors. Improvements in the valves of steam hammers, and steam, hydraulic and gas engines.

2965. L. Gonez, 15, Passage des Petites Ecuries, Paris, merchant tailor. A seat or chair forming also a travelling bag, for the use of travellers by rail or other way.

2966. F. Trachsel, chemical engineer, and T. Clayton, machinist, Manchester. Improvements in machinery or apparatus for obtaining light, heat, and ventilation, parts of which improvements are also applicable to other purposes.

2967. G. Hollins, Manchester, currier and strap manufacturer. Improvements in the manufacture of straps or belts for machinery.

2971. D. Scattergood, Nottingham, machinist. Improvements in circular frames for the manufacture of looped fabrics.

2972. P. F. C. Cheveron, and E. C. Eichenberg, Paris, Boulevard Rochechouart, 30bis, engineers. A new method of, and apparatus for, weaving Indian shawls and other figured tissues.

2973. R. A. Brooman, 166, Fleet-street, patent agent. Improvements in machinery for moulding and compressing artificial fuel, peat, bricks, tiles, and other substances. (A communication.)

Dated November 4, 1862.

2975. J. B. Francis, Hullard Hall-lane, Stretford, near Manchester, cabinet maker. Improvements in apparatus for raising and lowering window blinds, maps, and other articles, and for retaining them in position.

2976. J. Lefebvre, 54, Rue des Tournelles, Paris, architect. A new improved instrument for indicating angles or variations of level, and for measuring horizontal and vertical distances.

2977. F. Durand, Paris, mechanical engineer. An improved cotton gin.

2979. J. H. Johnson, 47, Lincoln's-inn-fields, gentleman. Improvements in hanging, arranging, and operating ordnance. (A communication.)

2981. J. Place, Over Darwen, Lancaster, spinner and manufacturer. Certain improvements in looms for weaving.

2983. T. Huntley, Manchester. Improvements in kitcheners and kitchen ranges, and in cooking and bath heating apparatuses.

2985. J. Shirt, Tamworth, Stafford, paper maker, and C. Briggs, Alders Mill, Tamworth, paper manufacturer. Improvements in apparatus for condensing the steam of high pressure steam engines.

2987. A. C. Dewies, Nicholl-square, Aldersgate-street. An improved lubricator.

Dated November 5, 1862.

2989. J. B. Thomas, Paris. Improvements in apparatus for working and controlling railway signal discs.

2991. J. Banwell, Watlington, Oxford. Improvements in apparatus for punching by means of hydraulic pressure.

2995. R. A. Brooman, 166, Fleet-street, patent agent. Improvements in spinning frames. (A communication.)

2997. A. V. Newton, 66, Chancery-lane, mechanical draughtsman. A new process of obtaining printing surfaces, dies, and substitutes for photographic negatives. (A communication.)

3001. J. J. Laveissière, 58, Rue de la Verrerie, Paris, merchant. Improvements in the manufacture of tubes of copper or other metals and alloys.

Dated November 7, 1862.

3010. C. O. Heyl, Berlin, manufacturer. Improved means and machinery to be used for the purpose of extracting fatty oils from oleaginous seeds, and for purifying the said oils, and for extracting the agents employed from the exhausted residue.

3012. A. V. Newton, 66, Chancery-lane, mechanical draughtsman. Improvements in repeating fire-arms. (A communication.)

Dated November 8, 1862.

3016. H. Kilshaw, Haslingden, Lancaster, spinner, and E. Lord, Rawtenstall, mechanic. Certain improvements in power looms for weaving.

3018. C. W. Spruyt, New Broad-street, City, civil engineer. Improvements in rails for railways.

3022. G. Kent, High Holborn, and E. P. Griffiths, High-street, Camberwell. Improvements in apparatus for reducing cocoa berries and other vegetable and animal substances to powder or pulp, and fof mashing potatoes.

Dated November 10, 1862.

3026. J. Whitaker, Leigh, Lancaster, agricultural implement maker. Improvements in machinery or apparatus for pulping, stripping, and slicing edible roots for cattle.

3028. S. Berrisford, Stockport, Chester, machinist, and W. Ainsworth, Stockport, Chester, overlooker. Certain improvements in looms for weaving.

3030. R. J. Chapman, South-street, Camberwell. Improvements in the manufacture of glass and emery paper or cloth.

3032. W. E. Newton, 66, Chancery-lane, civil engineer. Improvements in the treatment of maize or Indian corn preparatory to grinding the same into flour. (A communication.)

3034. T. G. Ghislin, Hatton-garden, importer. Improvements in the treatment of certain foreign plants, and in the application of the fibres derived therefrom.

Dated November 11, 1862.

3036. G. Davies, 1, Searle-street, Lincoln's-inn. Improvements in the construction of crinoline skirts. (A communication.)

3038. W. Palliser, Dublin, Captain of Her Majesty's 18th Hussars and Brigade-Major of Cavalry. Improvements in the construction of ordnance, and in the projectiles to be used therewith.

3040. J. J. Parkes, London-street, Paddington, bell-hanger and gas engineer. Improvements in lever bell pulls.

Dated November 12, 1862.

3042. W. Harper, Sharples, near Bolton-le-Moors, bleacher. Improvements in the construction of steam boiler and other furnaces.

3048. F. J. Clowes, 92, Southwark-bridge-road, engineer. An improvement in obtaining rotary motion.

3050. J. H. Thomson, Glenboig, Lanark, brick maker. Improvements in machinery or apparatus for finishing and dressing tiles and similar articles of clay.

3052. A. Graemiger, Wallenstadt, canton of St. Gall, Switzerland, manufacturer. Improvements in looms.

Dated November 13, 1862.

3058. M. Defries, Houndsditch, manufacturer. Improvements in the manufacture or construction of lamps.

3060. R. and P. Sykes, Huddersfield, machine makers. Improvements in rings used in machines for the continuous spinning, doubling, and twisting of wool and other fibrous materials.

3062. G. Davies, 1, Searle-street, Lincoln's-inn, civil engineer. Improvements in preserving provisions. (A communication.)

3064. E. Joseph, 134, Blackfriars-road, and J. Danks, 56, Webber-row, Waterloo-road. Improvements in the manufacture of brushes, brooms, and mats.

INVENTION PROTECTED FOR SIX MONTHS BY A COMPLETE SPECIFICATION.

Dated November 13, 1862.

3061. E. S. Ritchie, Brookline, Massachusetts, America. Mariner's compass.

NOTICES OF INTENTION TO PROCEED WITH PATENTS.

2012. D. Bateman. Carding wool and other fibrous substances.

2019. C. and J. W. Crossley. Washing and finishing textile fabrics.

2026. O. P. Drake. Vaporizing and aerating a liquid hydro-carbon to be burned for illumination or for other purposes.

2029. A. Couvreux. Centrifugal apparatus for breaking stones.

2030. J. Green. Producing signals.

2031. A. Couvreux. Casting stones.

2033. W. Dickens and J. Hewitt. Self-acting and hand mules.

2037. G. T. Selby. Superheating in tubes and tubular articles.

2045. H. Appleby. Armour plates for ships.

2060. R. Barrett. Working the damper of steam-engine furnaces.

2065. W. E. Newton. Preparing fibrous substances for combing. (A communication.)

2066. T. H. Saunders and J. Millbourn. Manufacture of paper.

2070. E. Bazin. Electric railway carriage signal.

2071. W. E. Gedge. Excavating or boring apparatus. (A communication.)

2072. T. Davey. Manufacture of gunpowder and explosive compounds.

2074. A. Naudain, J. Peacock, and W. H. Walton. Looms for weaving.

2082. J. Daniels. Artificial manure.

2088. T. King. Measuring malt, grain, and other granular substances.

2091. A. C. Vautier. Obtaining fibrous materials.

2099. R. Bell. Manufacture of bricks. (A communication.)

2107. W. H. Perkin. Printing and dyeing. (A communication.)

2109. M. Henry. Retarding and stopping carriages. (A communication.)

2112. J. Anderson. Separating gluten from starch.

2119. A. Lahousse. Construction of railway wheels.

2127. J. Walton and J. Moore. Ventilating and heating.

2136. A. Noble. Obtaining and treating compounds of alumina.

2139. F. Selby. Surface condensers.

2156. G. Nock. Self-acting crossing for railways. (A communication.)

2163. J. Benyon. Looms.

2171. W. Weild. Cutting, shaping, rolling, drilling, screwing, milling, and fluting metals.

2175. A. V. Newton. Machinery for planing metal. (A communication.)

2198. J. Townsend. Damping cotton and other fibrous materials and fabrics.

2206. W. G. Valentine and F. Levick. Generation of combustible gases for lighting and heating purposes.

2216. W. Clark. Rig, spars, and sails of ships and other vessels. (A communication.)

2316. W. E. Newton. Connecting plates, sheets, or slabs of metal, or other materials, and fastening the same on to framing applicable to armour plating for ships, vessels, or batteries, and to roofing and other similar purposes. (A communication.)

2404. W. Upfill, W. Morton, and W. Asbury. Construction of wheels and axletrees for carriages.

2458. S. H. Hadley. Manufacturing gas for illumination.

2832. C. G. Clarke. Garden shears.

2837. J. Duke, and J. Cleaver. Manufacture of cement.

2872. J. Carpendale. Producing chasing on metals.

2949. W. E. Newton. Carriages and beds of guns, mortars, and other ordnance. (A communication.)

2951. J. G. Marshall. Treatment of the straw of flax, hemp, and other similar vegetable substances.

3061. E. S. Ritchie. Mariner's compass.

The full titles of the patents in the above list can be ascertained by referring back to their numbers in the list of provisional protections previously published.

Opposition can be entered to the granting of a patent to any of the parties in the above list who have given notice of their intention to proceed, within twenty-one days from the date of the *Gazette* in which the notice appears, by leaving at the Commissioners'

LIST OF SEALED PATENTS.

Sealed November 21, 1862.

1509. J. Eastwood.

Note.—Specifications will be forwarded by post from the Great Seal Patent Office (publishing department) on receipt of the amount of price and postage. Sums exceeding 5s. must be remitted by Post Office Order, made payable at the Post Office, High Holborn, to Mr. Bennet Woodcroft, Great Seal Patent Office.

THE
MECHANICS' MAGAZINE.

LONDON, FRIDAY, DECEMBER 5, 1862.

AGRICULTURAL STEAM ENGINES.

We look forward to next week's Smithfield Club Show at Islington with some degree of hopefulness. For the last seven months the products of the leading agricultural engineers of the kingdom have been open to our inspection at Kensington. In doing our duty as recorders of progress in the mechanical manufactures, we have taken advantage of the long sojourn of the agricultural exhibits in the Eastern annex to examine and contrast their different designs, as far as this was possible without taking them to pieces, or seeing them at their work. We wonder, therefore, whether similar comparisons have been instituted by the different Eastern annex exhibitors, and if so, with what results. That exhibition was certainly a very remarkable one. Agricultural engineers are exhibiting all the year round at some place or another, and that not merely in England, but also on the Continent. The result was that they were quite in their element at Kensington. All the "stands" were arranged to produce the best possible effect. There were attendants to each one, with polyglot qualifications, and "catalogues" in all the languages of Europe; equally well prepared to attract a purchaser, whether in the shape of an English farmer, a French "agronome," or a German "econom." Certainly "agricultural engineers" do not hide their light under a bushel; we might even venture to hint that they are more inclined to place their light in front of the "patent reflector" of puffery. The advance in late years of this branch of mechanical engineering has, no doubt, been greatly owing to the competition induced at the various agricultural shows. They have what may be termed a democratic or levelling influence; an old-established firm cannot rely for success on its pedigree alone, and, as has been well said, "little blacksmiths have become great agricultural engineers." Nevertheless, the want of scientific precision and care evinced in conducting the trials of the implements by the Royal Agricultural Society, have done much to impede sound progress. The "fire-side farming" and "carpet engineering" rules, framed by the titled cyphers and the ignorant busybodies composing the council, have allowed things to subsist and flourish, that might certainly have been long ago eliminated. We would not be understood as saying that the best conducted trials could change the current of trade, could make or unmake a firm, but we do say that they ought to be a sure guide to non-engineering purchasers. It would take us too far at present to enter into an examination of the way in which these trials have been conducted, and the plan which should be adopted for the future. We will, however, offer some remarks upon the steam-engines of the two principal makers. These are Clayton and Shuttleworth, of Lincoln, and Ransomes and Sims, of Ipswich. Messrs. Clayton and Shuttleworth are well known for the number of agricultural engines they have turned out of their shops during the last few years, and Messrs. Ransomes and Sims, for the number of years they have been manufacturers. The engines of some of the other makers, bear a suspicious family likeness to those of the first named firm.

The mechanical details and the workmanship of the engines, from the Stamp End Works, are certainly very good. We should, however, prefer seeing packing pieces placed between the joints of the eccentric straps. An indifferent engine-driver would then not be so liable to screw up the eccentric clips so tightly as to break them on starting the engine. The straps also seem to us rather slight, and they would be altogether a better job if the oil cups were cast on them. Oil cups could also be forged on to the connecting rod straps. So many engines are made at the Stamp End Works, that this could be very well afforded. We have also noticed a slovenly plan these makers have of putting packing pieces under their governor brackets &c. A reprehensible omission in the Clayton and Shuttleworth engines consists in the fact, that the reciprocating parts are not counterbalanced. Is science at such a discount at Lincoln, that the sages of the Stamp End Works do not know the virtue of counterbalancing an engine, making, perhaps, 150 revolutions per minute? In some of the portable engines too, the exhaust pipe is carried back inside the whole length of the boiler. This may be termed an ingenious plan for *superheating* the exhaust on waste steam! Any shilling book on the laws of heat would enlighten the first best hand labourer on the results of such a plan.

The engines of Ransomes and Sims are, in some respects, a direct contrast to those of Clayton and Shuttleworth. They are neatly counterbalanced by a strip of metal being cast on to the fly wheels. The exhaust pipe of their ordinary portable engine is carried back outside on the top of the boiler, at the expense, however, of an ugly unmechanical flat casting to clear the crank. The workmanship is first class. The general arrangement and the details, however, of the Ipswich engine are very much inferior to its Lincoln rival. The crank of the portable engine is actually in the exact centre between the crank shaft brackets, being thus at a considerable distance from any bearing. The two ends of the connecting rod are formed in the following way:—The caps are united to the main rod by two bolts to each. This might, perhaps, pass muster some few years ago before slot drills were invented. The nuts to these are towards the inside of the rod; there are three holes drilled through each nut, and a pin is driven right through both nuts and through the connecting rod to keep them from getting loose. An ugly set off is left on the rod to make up for the weakening caused by the hole. It will thus be evident, that when the brasses get worn the engineman is tied to an exact 1-6th of the pitch of the screws in tightening up the brasses. These brasses are, by the bye, only turned where they fit inside, the cap and rod being bored out, and they have also too much opening between them to work sweetly for a length of time. The whole construction of the rod results in getting its shorter as it wears away, and is proportionately tightened up. We suppose that this is intended to be met by the cross head being actually *screwed* on to the piston rod, and by an extra clearance being left in front of the cylinder, thus involving continual loss of steam. There is no arrangement to take up the wear of the slide blocks or the slide bars, no packing slips between the bars, &c.

The crank, also, of the 15-horse stationary engine in the eastern annex was forged on to the shaft, and being of the same breadth all through, it looked very offensive to the eye. There are several other little things in the Ipswich engine that are not of first-class design, to which we will not further allude.

How is it that the Lincoln engine is so much superior in its details to its Ipswich rival? It appears to us that the answer is to be found in the fact that the Lincoln makers have probably taken for sample some good locomotive work. Locomotives are made by engineers for the use of engineers, and are put to work where slipshod details would involve the loss of hundreds of lives and thousands of pounds sterling. We consider that agricultural engine-makers would do well to take some more hints from the locomotive builders. We will instance Mr. Aveling's traction engine, which we believe is the best we have yet seen, particularly for agricultural purposes. What locomotive builder, however, would think of using a single cylinder on such an engine, thus involving a total powerlessness at the two dead points? Or would he allow the traction link to drag on the seams of his fire-box?

The problem of consuming smoke has been rendered a very simple and cheap affair on locomotives. How is it that nothing of this kind has been attempted for portable engines, with such facilities for this purpose? Portable engine builders always say that their endeavours are much restricted by low prices, when any addition is proposed to their engines. Surely a deflecting-plate, and a few firebricks in the fire-box, with a blower pipe in the smoke-box, would not cause much additional expense. The steam could also be raised much quicker, besides the smoke being prevented, or, at any rate, much diminished. Light, cheap, steam-packed pistons, are the sole ones now used in locomotive practice. All the designs of pistons we have seen for portable engines, have been of the old-fashioned massive character. The application of that elegant feed apparatus—Giffard's injector—would also be an improvement on portable engines. As the farmers have not the science to specify such an addition, we presume that the makers generally are not inclined to be over quick in taking, say, £8 of work off their goods for the sake of an improvement.

The continental portable engines in the Exhibition, with many defects, had some good points, that might be imitated more generally. Many of them had the engine on one casting, thus avoiding any alteration of the centres through the expansion and contraction of the boiler. The continental trade, to which the agricultural engineers of England are looking forward to as an important *debouché* for their products, requires economy of fuel. Accordingly, most of these foreign engines had expansion valves, and feed-water heating apparatus. Some of the portable engines we have seen in the Eastern annex, are, undoubtedly, below criticism. Mr. Disraeli has said that Londoners would never get a good architectural building till they had hanged an architect. We wonder whether farmers will have to apply the same recipe to some "noted" implement maker, before they get a good engine, and a simple thrashing machine.

H.

THE ATLANTIC TELEGRAPH.

Periodically, and as if by necessity, the great question of uniting Europe and America by telegraph, surges up and demands a practical solution. And it is quite natural that it should do so. No scientific industry of modern times has been more economically successful than the electric telegraph. There are now at work, in the United States of America, 40,000 miles of telegraph, extending from San Francisco, on the Pacific, to Newfoundland, on the verge of the Atlantic Ocean—where it is again proposed to land a cable which shall have its other end at Valentia Bay. There are upwards of 150,000 miles of working telegraph in Europe. A telegraph spanning

the Atlantic would unite the electric wires of America with those in Europe—as those in Europe are now united with many in Asia and Africa. Establish a telegraphic link between Newfoundland and Ireland, and instantly means would be taken to connect our West Indian Colonies and those of other countries with the mainlands of North and South America—thus bringing the whole industrial system of the two Americas into connection with that of nearly all the rest of the world. This question of an Atlantic telegraph is not merely economically and morally interesting to England and the United States, but it involves world-wide results. It would not only be the greatest triumph of science, but it would be the means of bestowing a rich inheritance of blessings on mankind. It is a benefit which the statesman, the capitalist, the economical reformer, the philanthropist, and philosopher, may heartily join hand-in-hand to promote. We believe it is possible and practicable; and if the Governments of England and the United States will render legitimate assistance, the great idea may soon be made a great fact.

It may be said that an attempt was made a few years since, and the result is a useless and perishing cable at the bottom of the Atlantic. It would be folly to pass over this significant fact in silence. The failure of that cable should not, however, be a rock to discourage, but rather a beacon to guide in the pathway of future efforts. It is almost certain that the Atlantic cable failed from controllable causes. It was manufactured and laid with undue haste. Conditions, moral and scientific, which should have been complied with, were trifled with, or neglected. In a second attempt more care must and will be taken. During the last few years, most valuable experience in the manufacture and submergence of cables has been gained. Improvements have taken place in the method of constructing cables. Any one who saw some of the specimens of gutta-percha in the eastern annex of the International Exhibition must have been struck with the great improvements made in the production of that material. We remember seeing one large sheet, as thin as note paper, and almost as transparent as glass. The gutta-percha, therefore, which was used in the first Atlantic cable was much inferior to that what may be used in a second Atlantic cable. We have improved processes for testing the capacity of gutta-percha and india-rubber, and also improved instruments for measuring the integrity of insulation. But, besides those improvements in the products and processes of manufacture, we can appeal to stubborn facts. Since the failure of the Atlantic cable, some of the most important submarine cables have been laid, including those from England to Hanover, from England to Denmark, from France to Algiers, and from Malta to Alexandria. All these, and others which might be specified, are in excellent working order. Out of the total number of 51 different submarine telegraph enterprises, which are all that have been entered upon, 44—comprising 5,133 miles of cable, and 8,906 miles of conducting wire—are at the present moment in perfect working order. Thirty of these 44 successful cables were laid by Glass, Elliot, and Co. That firm, we are informed, have never lost a cable. The Gutta Percha Company made, we believe, the "cores" of all the existing submarine cables. These facts are significant and instructive, and they may assist to explode the fallacies of theoretical critics, and put to flight the fears of cautious capitalists. At all events, they are encouraging data for future efforts. Up to the present time, the telegraphic enterprise has been successful. Let any one compare the prosperity and prospects of our telegraphic companies with a similar number of companies taken promiscuously from the commercial world established since 1851, and he will find the former the most prosperous. Considered in the light of speculation, telegraphic companies may confidently challenge comparison with any other class of companies. Considering, also, the comparative infancy of the science of electricity, and the engineering and other difficulties in the way of applying that science to commercial purposes, we are surprised that more mistakes have not been made, and that greater losses have not been endured.

Let us once more appeal to the testimony of facts. The inland ærial telegraph of the British Isles, without any foreign intercourse, send upwards of one million and a half messages per annum. There are still more messages sent by the ærial system of telegraph in the United States. The Submarine Telegraph Company sent, on an average, 470 messages a day in 1860; 630 messages a day in 1861; and during the present year the same company have averaged 844 messages a day. The months of July, August, September, and October, show separately an average of nearly 1,000 messages a day. We have not the returns by us to show the progress of the International Company. But we find, from a return of that company, that during the last three months, they have sent daily 524 messages. At the present moment, the actual rate of telegraphic traffic with the Continent cannot be less than half a million messages per annum, or, for 300 working days, a traffic of 1,660 messages per day. A cable, tying together the two Continents of Europe and America, would, of course, connect the telegraphic systems of the Old and New Worlds. Such a cable, if successfully laid, could not, we think, fail to pay. It would be travelling beyond our province to enter into details about the price of messages, and the number of them likely to be sent daily through an Atlantic cable. But as a misunderstanding has arisen in some minds about the capacity of an Atlantic cable for transmitting a given number of messages in a given time, it may be well to appeal in this matter to credible authority.

Mr. Varley thinks that certainly 12, or, more likely, 16 words, a minute, can be sent across the Atlantic, the copper conductor of the cable not being less than 5 cwt. to the nautical mile. Our last number contained an elaborate letter on this subject, from Mr. Varley. "By experiments," says Professor Thomson, in a letter, bearing date the 10th of November last, "made upon the old Atlantic cable before submergence, and by theoretical investigation, founded upon the principles demonstrated in my letters to Professor Stokes, on the 'Electric Telegraph,' October and November, 1854, and published in the proceedings of the Royal Society, for May, 1855, I am led to feel perfect confidence that a practical working rate of fifteen words per minute could be secured through a new Atlantic cable." Professor Wheatstone, Mr. Fleming Jenkyn, and others, have given similar testimony.

There is not much doubt about the possibility of laying a sound and working cable between Newfoundland and Ireland, and there is still less doubt about its paying, when once laid. The principal question for the moment is, *who* shall do the work? We feel satisfied that it can be done, and will be done, and that soon. If the Atlantic Telegraph Company do not perform it, some other company will. If England does not move in the matter, France will. The Emperor is known to be ambitious to connect his name with great industrial undertakings. Hence the encouragement he gives to tunneling the Alps, and cutting the Isthmus of Suez. Bridging the broad Atlantic with a cable would be a still greater achievement. England has hitherto played the most prominent part in endeavouring to accomplish this work, and we sincerely hope our countrymen will not be deterred in a second attempt, because we have failed once. When the vast commercial advantages involved in the undertaking are considered, we are astonished that the matter has been permitted to sleep so long. The benefits the Governments, and, consequently, the people, of America and Europe, would realize, are incalculable. Antagonistic and irritable feelings, have, for some months' past, found utterance on both sides of the Atlantic. There has been a reciprocity of unenviable compliments passed between the two peoples, which may be the seeds of future angry and expensive disputes. The leading organs of the press, on both sides, have, by mutual exaggeration and recrimination, assisted to produce misconception and estrangement. We wish to see a healthier feeling produced, and we think that an united effort on the part of the peoples and the Governments of the two countries, for an Atlantic telegraph, would lead to such a result.

It would, perhaps, be contrary to true economical science for the Government to give an unconditional guarantee; and, after reflection on the subject, we are led to question the rightfulness of such a policy. But as the Governments would be co-recipients of the advantages from such telegraph, we do not see why they may not be co-workers in its establishment. If the Government were to advance a specified sum to be taken out in work to be subsequently done, or even if the Government, as an encouragement, were to take shares, we do not see that they would be going beyond their legitimate province. Of course they would not do this in the hope of realizing commercial advantage, but for imperial purposes. The Government are, in fact, the proprietors of the principal submarine telegraph in existence. The Malta and Alexandra cable, which is 1,535 statute miles in length, was laid by the Government, and is national property. The main object in laying that cable was to promote more rapid intercourse with our vast Indian empire. In asking the Government to become partial proprietors of another cable, whose existence would be of such importance to the whole interests of civilization, we are only asking them to take another step in the same direction they have already taken. Let the Government, then, only advance one-sixth part of the sum consumed in the Malta and Alexandria cable, towards another for the bed of the Atlantic, the American Government will do likewise, and the great work will soon be done. Every one, we think, must admit that encouragement of some sort should be afforded by Government. The plan we have suggested is, we think, but little liable to objection, and considering the progress of science, the large and increasing demand for telegraphic communication with America, and the momentous issues at stake, we hope and believe that before a few months are passed away, some definite and certain action will be taken towards the accomplishment of the most magnificent industrial enterprize of the nineteenth century.

J. P. E.

Mr. Bullions, an engineer on board her Majesty's ship "Psyche," was killed the other night, at Marseilles, in a *melee*, while his companion Mr. Gray, an engineer belonging to the same vessel, was injured so severely that—according to the latest accounts—his life was despaired of

NAVAL GUN AND ARMOUR EXPERIMENTS AT SHOEBURYNESS.*

[*We are informed by "An Official," that the frames of the target penetrated by the Whitworth shells are the same distance apart as those of the "Warrior." Correcting this slight difference, which amounts to one frame less in the length of 10 ft., he admits that two of the plates, being 5 in. thick, instead of 4½ in., and the target being supported at both ends with solid timber 7 ft. in thickness, the resisting force, and therefore the triumph of the Whitworth projectile, was so much the greater.*]

(Continued from page 325.)

The experiments on Friday, the 14th ult., were marked with peculiar interest. Questions which former trials left in doubt, and which are respectively the subject of totally opposite theories, were submitted to the searching test of cannon balls, and conclusively solved. The comparative penetrating force of smooth bore and rifled guns, the nature of backing to armour plates, the effect of rigid or elastic resistance, and deflection, received a practical elucidation of more value than the profoundest deductions of professional science.

This day's experiments were so imperfectly reported in *The Times*, it is desirable they should be correctly described, the questions they determine referring to a branch of public expenditure of enormous amount.

Our report does not follow the order of the proceedings, but gives every series separately. From one cause or another, and to save time, each set of experiments was not completed by itself, but suspended and resumed as the guns were ready to be discharged.

In these Shoeburyness campaigns, there is more of tactics and manœuvres than might be supposed. The chairman of the Iron Plate Committee commands the movements; the commandant of artillery executes them; a mounted aide-de-camp carries orders to lay and point the guns. Not the least interesting part of the operations is the working and registering of an ingenious, but simple apparatus, for determining the velocities of projectiles, which is under the management of a young officer of the Royal Engineers, who is reputed to be a good mathematician. The apparatus consists of a frame, across which thin copper wires are stretched horizontally in parallel lines, and of a pendulum of which the vibration is measured. The frame is placed a few paces in front of the gun, or the target, accordingly as the initial or impact velocity is required. The wires, which are so close together that the projectile cannot pass between them, are connected with, and act upon the pendulum, by means of an electrical current passing through them. Any one of these wires being broken by the passage of the shot, the pendulum indicates the force of its vibration, and by working out a mathematical formula the velocity of the projectile is ascertained to the 1,000th part of a foot per second.

The main business of the day was the trial of the comparative force of the smooth bore 68-pounder and the 70-pounder rifled Armstrong. This series of experiments was planned by Sir William to support his favourite theory.

It will be remembered that on all previous target trials, and notably those of the "Warrior" section, the 110-pounder rifled Armstrong solid shot were less effective than the old smooth bore 68-pounders. Taught by experience, Sir William has changed the form of the head of his projectile, which, instead of being conical, is now globular, having the rear part cylindrical; and he maintains that the round heads will beat the flat heads. That is a question which remains to be solved; but the trials we are now referring to have proved that the round-headed shot from a rifled gun, has greater penetrative power than the spherical shot from a smooth bore.

The rifled Armstrong and the smooth bore were fired at 200 yards range, against 5-inch plates backed and supported on the plan of the "Warrior," with equal quantities of powder (the service charge of 16 lb.), and equal weights of shot (68-pounders.) The impact velocities obtained by several discharges from both guns, varied from 1,430 to 1,450, and 1,480 ft. per second, and gave the following results. The rifled roundhead made an indentation 8 in. in diameter, and 2·6 to 2·7 in. in penetration, and the spherical smooth bore an indentation of 9 in. diameter and 2 in. penetration, giving the superiority to the former in the proportion of 26 or 27 to 20. The damage to the plate by the former was greater, as shown by circular cracks round the circumference of the indentation, which were not produced by the latter. These trials were fairly conducted, and the results appeared to give much satisfaction to Sir William Armstrong. They have redeemed the character of the rifled shot as a battering projectile, and they show what little dependence is to be placed on experiments, unless all the circumstances under which they are made are carefully considered. The conical nose of the Armstrong 70 and 110-pounders, used in the first experiments, was the cause of their inferior effects, just as the flat head is one of the causes of success of the Whitworth shot and shell. The form of the projectile, it is therefore evident, is of no less importance than the nature of the gun; and, it is equally clear, from the effects of hardened steel, as compared with cast and wrought iron projectiles, that the material of which they are made is an element of the greatest consequence in determining their destructive force. Sir William Armstrong, it is understood, is confident that hard steel round headed shot and shell, on his principle of rifling, will surpass the Whitworth flat heads.

The next series of experiments we have to record refers to backing of armour plates. The effect of artillery on plates depends, perhaps, as much upon the material on which they are bedded, as upon the quality and dimensions of the iron, and the force of the projectiles. Rigidity of backing would appear to be a desideratum, experiments having proved that elasticity aids penetration. Hard wood has been used to support the armour of all the iron-clad ships hitherto constructed; but an impression prevails that a tougher and more unyielding substance might be advantageously substituted for it. Strange to say, paper has been thought to possess these properties, and in the form of millboard was tried on Friday in competition with wood. Two small targets were arranged for this purpose by the Special Committee. These, for distinction, we call A and B. Each consisted of a 1 in. plate, 4 ft. by 3 ft., firmly secured by three vertical iron bars fastened with screw bolts to a timber butt 2 ft. thick upon a backing of 14 in., which for A was composed of sheets of common millboards barely ⅛ in. thick, and for B of teak. With this difference the targets were precisely similar.

No. 1 shot, a 6-pounder Whitworth 5½ in. in length, and 2½ in diameter, was fired at A. It pierced clean through the 1-in. plate, and about 2 in. into the millboard, leaving 2½ in. of its length protruding outside. Its penetration was, therefore, 3 in. No. 2 shot, precisely the same as No. 1, with the same charge and at the same range, was next fired at B target. It passed entirely through the 1-inch plate, making a larger and a ragged hole, and buried itself completely in the teak, which was split through to the top. Fragments of the broken iron were visible 2 or 3 in. inside the orifice of the hole. The extent of penetration could not be ascertained without breaking up the teak, but it certainly was more than double that into the millboard. This result excited some surprise; and as one trial was not considered a sufficient test, the experiment was repeated with a 6-pounder under the same conditions as the former one, and with the same result. A 12-pounder Whitworth was then fired at both targets. In each case the shot pierced through the plate and backing, and so deeply into the timber butt that, without breaking up the latter, the comparative penetration could not be ascertained. The visible difference externally was that the hole in plate B was larger and more ragged than A, showing that the wood backing afforded less support than the millboard, and the fibre of the wood closed behind the projectile, whilst the hole through the sheets of millboard was open, so that a rod could be thrust into it. The presumption from the effect of the two 6-pounders is, that the penetration of the 12-pounder was less into A than into B; and, from the decisive results with the former, we may fairly conclude that the victory rests with paper over wood. This trial was made under conditions unfavourable to the former. The sheets of millboard, which was of inferior quality and loose texture, were placed loosely together without any compression but that of the screw bolts which fastened the supporting iron bars. The resisting force of this material has attracted so much notice that further experiments will be made with hard cardboard of greater density, and it is hoped they will afford still better results. The credit of originating the idea of paper backing is due to Mr. Mallet, who suggested it some time ago. But probably it would not have been tried but for the abolition of the paper duties. Mr. Gladstone, in enumerating the uses to which the article might be applied, little thought that, in combination with iron, it would supplant "wooden walls" and become an essential element in our national defences. We fear we shall be accused of romancing in stating that the hulls of war ships may possibly be constructed of *papier maché*, but the fact is, that such a proposition is seriously mooted in a quarter which commands respect.

The object of the third experiment was to test the plan of a Mr. Felton, who, unaware, apparently, of previous trials of the elastic system, submitted to the Iron Plate Committee a small target, consisting of alternate layers of iron, india-rubber, *and vulcanite*, three plates, ⅜ in. in thickness, being arranged, one at the front and back, and one in the centre, with the elastic materials between them, making a total thickness of 7 in. An iron plate, full 1⅛ in. in thickness, the equivalent in weight, and of the same length and width as Mr. Fenton's target, was prepared by the committee. These small targets were fired at alternately with a 1-lb. wall piece. The shot, which made an indent only 2-10ths in. in the committee's plate, passed through the outer ⅜ in. plate, and penetrated 4½ in. into the body of Mr. Felton's target. Both were then submitted to a severer test, with a 6-pounder Armstrong, a shot from which broke the committee's plate, but failed to pass through it. Another shot from the same gun smashed right through the elastic target, which was completely demolished. This is another example of the inefficiency of an elastic resistance to projectiles, and proves that rigidity is the true principle for the construction of armour.

* Want of space prevented us inserting this last week.—Ed. M. M.

The object of the last of the experiments on Friday was to settle the vexed question of "deflection." Notwithstanding the previous experiments by the committee, which tended to discredit the theory, the advantages of deflection has been so much insisted upon, that they deemed it expedient to set the question at rest by a further and conclusive trial. Two plates, about 4 ft. by 3 ft., and 2½ in. in thickness, were fixed one above the other, on a stout wooden frame, at an angle of 45 deg., and were fired at with Whitworth's 12-pounder elongated hexagonal shot, and a charge of 1¾ lb. of powder. The first two discharges produced no effect on the plate struck, except a mark on the face, not amounting to an indentation, and a slight crack behind.

The shot were supposed to have glanced off. This, however, excited much surprise, when a third shot, of the same kind, being fired against a vertical plate, it was broken up, and proved to be cast-iron. It was then discovered that these were pilot shot, not intended for destructive effect, but only to take the range. The Whitworth hardened steel flat-headed 12-pounder, with a charge of 1¾ lb., was now brought into play. The effect of the first shot was remarkable and decisive. It struck the centre of the upper plate, penetrated through the iron completely, but its entire length did not pass through. The hexagonal twist of the rifling arrested the passage of the projectile, which stuck fast in the plate, one end protruding in front and one behind, fracturing the back of the plate considerably. Another shot of the same description also penetrated the plate, making a hole right through it, but apparently from the same cause of obstruction as the last, it rebounded from the plate, and flew back 25 to 30 yards into a ditch. A third 12-pounder not only penetrated, but passed clean through the plate, and was picked up behind the target.

Every one of these projectiles sped its way in a horizontal line, and straight as an arrow, through the plate, without the slightest deviation from its course. Being of an elongated form, 8 or 9 in. in length, and a little over 3 in. in diameter, with flat heads, they presented the conditions which are regarded by the advocates of the theory as most favourable to deflection, and yet *there was none*. These results leave no doubt that the deduction of the Iron Plate Committee from their former experiments was correct. The effect of an inclined plate is simply to increase the horizontal thickness to be penetrated by the shot, and the increase is in proportion to the angle of inclination. Practically, a given weight of plate with a given vertical height, placed vertically or inclined, offers the same resistance, so that nothing is gained by the angular arrangement devised by Mr. Jones, of Liverpool, applied to the "Merrimac," and proposed for the cupola ships, or even from the round tower principle. It follows that the common notion of deflection is an error. Abstractedly, the resisting force or a plate is in proportion to its thickness. What is called deflection exists only when the penetrating force is insufficient, in which case repulsion takes place at an angle, and is called deflection, if the line of the blow is not perpendicular to the plane of the surface struck. If the projectile force is sufficient for penetration, there is no deflection, and there is no rebound.

The Iron Plate Committee have done good service in clearing up this question, which has given rise to so much discussion, and created notions of a defensive system which, if our conclusions are correct, will prove to be delusive.

DEEP-SEA TELEGRAPHY.

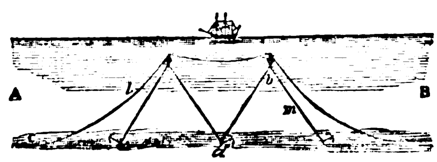
TO THE EDITOR OF THE "MECHANICS' MAGAZINE."

Sir,—I have to request the favour of your inserting in the Mechanics' Magazine the following proposals for overcoming some of the most formidable difficulties by which deep-sea telegraphy has heretofore been beset, premising that they have already been embodied in a communication addressed by me to the chairman of the Atlantic Telegraph Company.

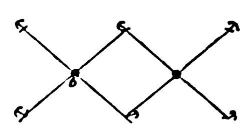
I believe I am correct in stating that, in all deep-sea lines, the risk of failure and the attendant amount of pecuniary loss increase directly with the distance to be traversed at a single stretch; the rupture, either of the conducting wire or insulating covering, being fatal and irremediable.

I propose materially to diminish the danger to which a submerged cable is liable, and altogether to preclude such a calamity as its entire loss through injury sustained at one or more points, by the simple expedient of *anchoring* air-tight metallic buoys, in pairs, at long intervals, of from 50 to 200 miles, and attaching them by lines to the telegraphic cable in such manner that, whilst both buoys and lines shall be raised near enough to the surface to be within easy grappling range, they shall be beyond the influence of tidal or other superficial disturbing agencies; each buoy, moreover, being so far separated from its fellow as to enable a ship to hit off the interval with readiness in favourable weather.

The subjoined diagram, representing an extreme case as regards depth, will, perhaps, serve to convey my meaning more clearly than mere descriptions :—



Let A B represent a vertical section of the sea, the depth being 1,760 fathoms, or about a couple of miles; *b b*, a pair of buoys, of sufficient size to support not only their own mooring lines, *m m*, but likewise the line, *l l*, suspended by them and attached to the telegraphic cable at *c c*. Here the two buoys are moored to three anchors, resting in a linear series, the centre anchor giving attachment to two of the mooring lines. As this might, however, allow a certain degree of oscillation, it would, perhaps, be more desirable to employ a double series of moorings, six anchors, instead of three, being laid down, so as to form two parallelograms, above the centre of which the buoys, *b b*, would then be securely retained in a fixed position, as shown below :—



Without, however, discussing minor details, as to the distances by which the buoys should be separated from each other and from the next series, the most efficient mode of mooring, and the expedients for determining the precise portion of the suspended line which may happen to be struck by the grappling iron, and clearing it from the buoys without risk of fouling the moorings, I trust I have said enough to show that my scheme is neither chimerical nor hampered by any doubtful conditions beyond those incident on its cost.

It may prove an expensive addition to the already costly machinery of deep-sea telegraphy. But I have only to request those who adduce this objection to "remember Lot's wife"—in the shape of half-a-million's worth of cable laying dormant at the bottom of the Atlantic. I presume the outlay incurred in a system of buoyancy such as I advocate, even had it added another £20,000 to the gross expenditure, would be deemed a first-rate investment, were but half the lost cable thus rendered recoverable.

In conclusion, I would observe that the novel and leading feature in my system of buoying consists in its being effected, not from the surface of the sea, but *from the bottom*; thereby avoiding all disturbing influences, offering the greatest facilities for permanently suspending from the bottom such portions of the *cable itself* as may have to traverse abrasive or otherwise dangerous tracts, and, virtually, yielding the advantages of a series of short lengths.

I am, sir, &c.

G. C. Wallich.

December 3, 1862.

ON THE INFLUENCE OF SCIENCE ON COMMON LIFE.

Some time since Baron Liebig delivered an address before the Academy of Science, of Munich, on the "Influence of Science on every day Life." The speech was in every way worthy of the reputation of the great German philosopher, who, from the solitude his laboratory at Giessen, has exercised such an influence on the destiny of the age.

But few men in practical life (says Baron Liebig) and engaged in applying the results of pure science to their own special requirements, are in a position to recognize the exact way in which science has increased their riches and extended their powers. When chemistry, however, is seen to furnish the farmer with recipes for manures applicable to all soils, or with remedies against the potato disease or vermin, or the blight and rot of wheat, but few men can still remain ignorant of the true source of these improvements. Pure science, nevertheless, does not work for the few, but for the many; it works, in fact, for all mankind. The domains of science are founded on the great truths that govern and direct mankind; science enquires whether existing beliefs answer to the laws of nature and of reason, and it replaces imperfection by completeness. Science transforms and improves the knowledge of man, but each intellectual stage requires ages for its completion, and generations are born and pass away before old errors give place to newly-discovered truths.

The roots of a plant draw nourishment from the earth if it be sufficiently diluted with water, but the plant is killed by concentrated food. Heat and sunlight also must lend their aid that the seed may in time increase into the fruit-bearing tree. A similar law of nature has sway over the growth of ideas in the mind of man. An abstract notion, although of itself a fruit, is not the fruit-bearing tree, but rather its seed, and, also like the tree, it requires warmth and culture and suitable nourishment that it may fructify in its turn. There are ideas that will rouse up for a time whole nations, but they pass away, leaving no trace behind. They die away like the green bough of a tropical tree placed in water. It gives forth leaves and flowers, but having no root in the ground can never bear fruit. The fruits of progress enjoyed by the present have their roots in past generations, and the new truths that we acquire will only bear fruit in our children's time.

The slightest improvement in any trade requires time before it can find its way amongst the mass of mankind. The simple idea of using phosphorus to kindle a light, originated in the middle of the last century. It has taken 50 years to produce practical results from the experiments, aiming at the use of gunpowder in a closed chamber; this being the basis of **all (?) the late improvements in fire-arms.**

Ruling error is so difficult to overcome, because it is received as truth by the majority of mankind. This is not, however, the only reason that a truth makes its way so slowly into common acceptance. Habit, want of thought, and the inborn dislike of mankind to the exercise of their intellectual powers, are impediments of no less importance. The most ignorant labourer knows that the raindrops, falling on his dung-heap, bring with them silver pieces. He knows that the refuse, sweltering in the ditches of his village, and poisoning the air, would fructify his corn fields. He, nevertheless, stands by with indifference, like his father before him, and, for the same reason, because things were the same in the good old time. In the same way (continues Liebig), the municipalities of large cities spend annually immense sums on their sewerage. They put **the means of reproducing the bread of millions beyond the reach of the farmer. The farmers look on this with indifference. They however think it a praiseworthy undertaking to fetch the same elements from America, several thousands of miles away.**

The growth and extension of better views as to these matters require time. This increase of knowledge will result in the increase of human power, and favourable circumstances may in some cases hasten its development. If education has not given to any nation a power to examine and select the teachings of science, then the attempts of the enlightened few are lost in trying to apply these truths, and they are rejected by the masses as something strange and unheard of.

In such a country, even if Wisdom herself were to go from house to house offering her services, the poorest of the land would reject her in their folly. They would say that her help was importunate, that it was not wanted, that they knew enough, and were in want of other things than mere knowledge.

There are plenty of instances of farmers, even men of education, having refused to try experiments with artificial manures that had been offered them for this purpose by agricultural societies. They wished to have them gratis, and to be thanked for using them.

Such a state of things, however, is passing away. It is impossible for a nation to refuse to advance, and to reject the power and wealth in the gift of science. That God, in His own good time, causes the seed to ripen, and that the True and the Good are imperishable, remain as eternal truths.

But, even in countries where the truths of science are willingly received, the men who most put them to use are often ignorant as to their source. When, after years of opposition, a scientific truth gets into general acceptance, the generation that has grown up in the midst of these new ideas is unaware that they result from a series of gigantic labours. The telegraphic clerk is little aware that the small apparatus he works is the result of toilsome research by hundreds of sagacious minds during half a century. He little knows that it embodies a series of facts that required to be discovered and established before even the idea of the apparatus by means of which he fills a useful and comfortable position in society could take its rise.

The fresh generation believes that the present state of things has always existed; it cannot believe that things now received as intelligible, true, and useful, have been scouted as useless, **false, and unintelligible. The great mass of** mankind has no comprehension of the difficulties that accompany researches for extending the domains of science. It may even be said that the inborn love of men, in general, **for truth would not suffice to overcome the difficulties in the way to any great result, did not this impulse rise to the dignity of a passion in the breasts of the votaries of science—a passion giving force and increase to the power of their intellect. Such researches are undertaken without hope of gain, or even of thanks.** The successful man in these researches has but seldom the good fortune to reap their useful application; he cannot sell his harvest in the market of life, for it is without price; and it cannot be made to order, nor can it be bought,

Even the most powerful influences of science on man's mind and every-day life, are so slow and gradual in their progress, as to be scarcely noticed by the superficial observer. But the enlightened man knows that no world progress is possible without the aid of science. He knows that the reproaches directed against the practical usefulness of theoretical knowledge fall on society, and not on men of science. Such men follow, undisturbed, their career, without anxiety as to the future usefulness of their works; a usefulness not bounded by the frontier lines of a single state, but covering the whole universe in its expanse.

IRON WALLS AND NAVAL GUNS.

TO THE EDITOR OF THE "MECHANICS' MAGAZINE."

SIR,—The fear of exciting in the minds of your readers that utter disgust, which, according to our great poet, is created by "damnable iteration," has deterred me from noticing the diatribes of some of your correspondents, who seem to think more of dreamy and inexplicable theories, than of practice and facts. If I engaged in a contest with such adversaries, I should imitate Don Quixote, who converted windmills into giant warriors, imbued with intelligence; and harmless sheep into armed batallions. The worst punishment that could be inflicted upon those writers would be to print their letters, which I conclude, in pity to them, and in mercy to your readers, you have declined to do. I leave to the theoretical and ponderous Mr. Cheverton the luxury of the last word, and I respect the undiscriminating wrath of Mr. Thos. Gale, whose indignation against the Admiralty for refusing to adopt his wooden "steam ram," makes him commit the eccentric blunder of classing "Civilian" among the supporters of that inscrutable department; when Mr. Gale ought to know, from the whole tenor and arguments of the letters on "Iron Walls," that precisely the reverse is the case. Without any further notice of individual criticism, I will apply myself to some important points at issue in the controversy on guns and armour.

DEFLECTION.

The vulgar notion of deflection is that an inclined or angulated surface possesses or creates a repelling power. If that is not the sense in which deflection is advocated as a means of resistance to penetration, I shall be glad if any of its supporters—Mr. Jones, Mr. Richardson, Capt. Coles, or others—not for my enlightenment, but for the benefit of the public, will expound their theory. Unless they abandon it, they are bound to respond to this challenge.

Not to shirk the question myself, I affirm that, in the sense above described, deflection is—I cannot call it a *power*—an imaginary source of causation. It may, I think, be properly described as angular or diagonal repulsion. If a projectile be thrown against the level surface of a body which it cannot penetrate in a line perpendicular to the plane of the latter, it will rebound on the same line. If the line of projection be at an angle to the surface, or if the surface itself be angulated or inclined, the projectile—the force being insufficient for penetration—will rebound at an angle. This action or result is called deflection, and the phenomenon, as we see it exemplified in the games of tennis, or billiards, has come to be regarded as a proof that the force of the blow is diminished or warded off, because it appears to glance aside. But is it possible that either the line of direction of the projectile or the position of the plane which receives the impact can alter the force of penetration or resistance? The absurdity of this proposition, when the former force is greater than the latter, becomes more obvious.

Applying this rule to projectiles hurled against iron plates, I venture to form the following conclusions:—If the projectile force be sufficient to penetrate the plate, there will be no deflection. The plate will be pierced through and through in a straight line, whether it receive the impact perpendicularly to the surface or at an angle. If the penetrating force be insufficient—that is to say, if the plate repel the projectile—the repulsion will be in the same degree whether the plate be struck point-blank or obliquely. This opinion may be regarded as a scientific heresy or a theoretic blunder; but I appeal to facts as demonstrated by the experiments of the Iron Plate Committee. The increased thickness of plate to be traversed in a horizontal line, if it be inclined instead of perpendicular, is another question, which resolves itself into the fact that, *cæteris parabus*, a greater penetrating force is required, so that the plate will repel or stop the projectile, but that is not what is meant by the disciples of the deflection school.

Coming to the practical view of the object of an inclined surface of iron plate for fortification, we must look to the vertical height of the defensive wall; and we find that taking the same quantity, and therefore the same weight of iron, the thickness of the plate must be diminished in proportion to the increased length of the incline, as compared with the height of the vertical plate, and that thus the supposed advantage of the so-called deflective principle is neutralized. I shall not at present carry the exposition of this point further. I believe, I am prepared to prove that, not only is there no gain, but there is a positive loss of resisting force, in applying a given quantity of iron for fortification in an inclined instead of in a perpendicular position.

PENETRATION.

The punching process, with which I have familiarized artillerists and engineers, as an apt illustration of the effects of ordnance on iron plates, gives us the law which regulates those effects. Some great authorities, amongst them Sir William Armstrong, have denied the correctness of the comparison. So shrewd a man, and one so ready to abandon any method when he finds a better, as well as other sceptics, will no doubt change their opinion and acknowledge the theory that, to pierce a plate with shot or shell is nothing more or less than to drive a punch through it with the force of gunpowder. This being so, all doubt and uncertainty as to the rule for resisting artillery with iron fortifications are removed. To punch through a plate, two preliminary conditions are required—sufficient penetrative force and hardness, combined with cohesive strength in the material of the punch, superior to those properties in the plate. The first is a *sine qua non*, and is assumed to exist in all my arguments. The law of penetrative force of a projectile, which appears to be determined to the satisfaction of artillerists, is represented to be its weight multiplied by the square of its velocity, which is regulated by the charge of powder. Here we have an intelligible formula which anybody can work out. As to the second point, we need only to reflect upon the established practice of using a steel punch to perforate boiler plates, and the results obtained by the Whitworth bolts, to be satisfied that it is as imperative as the first.

Having settled the conditions precedent, w

come to the punching law, which determines that you must make the resisting strength of your armour greater in effective thickness than the diameter of the projectile. If you do that, you will resist the penetrating effect. The *effective* thickness may be composed of the absolute thickness of the external armour plate proper, by itself, or of the latter thickness, fortified by the backing on which the armour plate is bedded. As the medium of so fortifying the plate, I have so often and so emphatically condemned wood, that it has been designated my "crotchet," or "hobby;" but, in sober seriousness, I will ask, can *wood* offer any adequate resistance to the bulge of the armour plate at the back of the area of impact, or impart any efficient local strength to the plate? If you adopt an elastic or yielding backing, and reject a hardened rigid one, you are brought to this dilemna—you facilitate penetration.

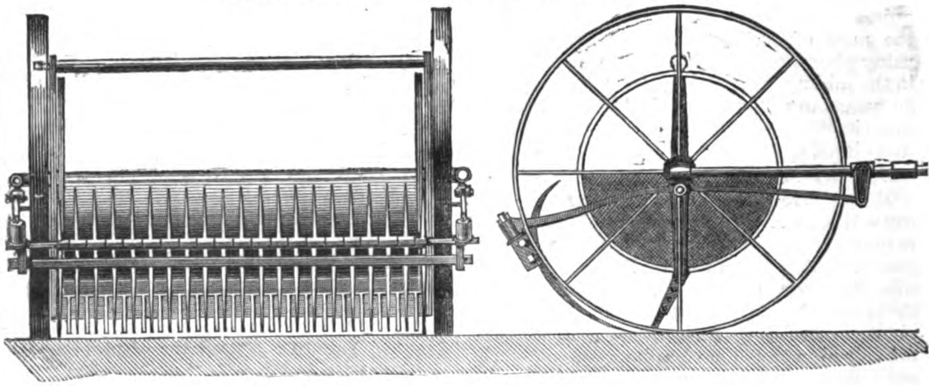
For the moment I will pause, that my contradictors may reflect upon and digest that proposition. I have been twitted with the mania of demolishing theories, without propounding one of my own. I have long had one under my notice, but I have abstained from submitting it to public discussion, for the sufficient and sincere reason that, in promoting a controversy on naval armour, in your columns, I was as much at sea on the true principles of its construction as all the world; and being, as I acknowledged from the first, unscientific, and unprofessional, I was diffident of my own opinion, and undecided as to the real merit of a system which appeared to offer some advantages. Numerous experiments, however, have thrown light on the subject, and in an early number of your invaluable journal —invaluable as the field of free discussion on science, arts, and manufactures—the system referred to shall be submitted to the criticisms, which I have so freely, and, I fear, sometimes, in the heat of argument, so unceremoniously exercised upon other plans. I hope I have given offence to nobody. I have sometimes retorted when I have been assailed, but in these controversies we must give and take.

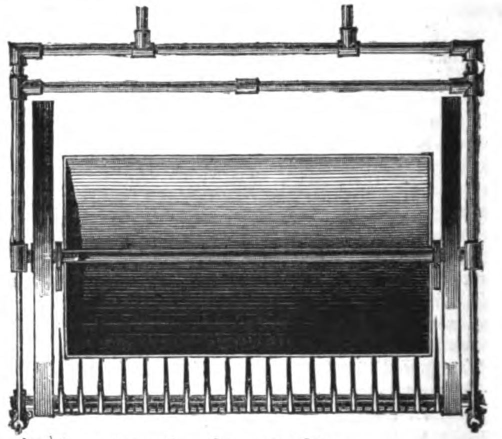
CIVILIAN.

NEW PRINCIPLE OF SHIPBUILDING.

On Monday last a vessel was launched from the yard of Mr. J. Robinson, Duke's Dock, Liverpool, in which a new and important principle in shipbuilding has been introduced, and which has attracted considerable attention amongst gentlemen interested in the trade. The vessel draws about 2½ ft. of water, will be able to proceed to sea without any ballast, and will take the ground with perfect safety. She has the peculiarity of being almost flat-bottomed, and from this and other things she is expected to be capable of carrying a very large quantity of cargo in proportion to her tonnage. Her bilge will take the ground at the same time as her keel, which is planked of wood 10 in. in thickness. Her dimensions are—length, 100 ft.; breadth, 22 ft.; depth, 12 ft. 3 in.; and she will carry 440 tons dead weight at a draught of about 11 ft. She will be rigged as a brigantine with wire rope manufactured by Messrs. Garnock, Bibby, and Co., of Liverpool, but the mainsail will not have any "gaff," the head of the mainsail hoisting up to the head of the mainmast, and gaff-topsail from the head of the maintopmast to the end of the main boom, which it is considered will be an improvement, and add to the vessel's sailing powers. The vessel is intended for the conveyance of machinery, and has an exceedingly large hatch with two beams at the end close together, with a large iron rod passing through timbers and screwed on a large iron plate, which makes the beams of the requisite strength without the introduction of stanchions. The vessel has been built in a very short time, and Mr. Robinson states that he could build a ship of 500 tons of the same model in six weeks, with the same number of hands that he is now employing. The vessel is the property of the builder, who is the owner of other vessels, and has experienced the difficulty of vessels built on the old model of entering ports where there is shallow water—a difficulty which he thinks this vessel will obviate. The launch was effected in capital style, the vessel gliding gracefully into her future element amid the applause fo the spectators.

DRUMMOND'S PATENT REVOLVING RAKE.





DRUMMOND'S PATENT REVOLVING RAKE.

A patent has just been obtained by Mr. P. R. Drummond, of Perth, N.B., for a revolving rake. The accompanying engravings represent the invention. The implement is intended for lifting objects, such as stones, hay, felt, corn rakings, turnips, potatoes, or soil from the ground into a cart without the aid of the human hand.

This is accomplished in the following way:—A cart, similar to the common two-wheeled cart, has a rake very nearly the same as the common horse rake trailing behind, the teeth of which have the same circle as the periphery of the cart wheel, and is drawn forward exactly between them. The shafts of the cart are fixed outside the wheels, and between the wheels and the cart two arms are carried round on the same centre, between which the revolving rake is fixed. Thus, as the cart is drawn forward, the teeth of the revolving rake are carried round the cart from front to back and upwards between the teeth of the trailing rake, carrying whatever substance may be collected on them, and when the revolving rake reaches the centre of the cart the teeth gravitate and drop their contents into the cart, and then pass on at the pleasure of the conductor. A revolving rake for the purpose described, and similar in principle, was exhibited in the eastern annex of the International Exhibition.

SOLID DRAWN GUN BARRELS.

On Tuesday, by the permission of the court of the company, some very interesting experiments were made at the proof-house of the Gunmakers' Company, Whitechapel, on a fowling piece and rifle barrel made by the new process of solid cold-drawing, of which Messrs. Christoph, Harding, and Hawksworth, are the patentees. By this process the metal is drawn cold by means of the hydrostatic ram, and thus a saving is effected to the extent of one-half the metal now consumed by the hot process. For instance, about 10 lbs. of metal is now used in making an Enfield rifle barrel, which when made weighs only about 4¾lb., the remainder of the metal being consumed in the manufacture. By the present process two rifle barrels can be drawn from the same amount of metal, equally strong in every respect to those now made. The barrels tried that morning were drawn from a new kind of cast steel, and subjected to the following proofs:—

Rifle Barrel.

First proof......	7½ drachms of powder 2 wads 1 ball of 520 grains ...	No effect
Second proof...	Same powder 2 balls	No effect.
Third proof ...	10 drachms of powder 3 balls	No effect.
Fourth proof...	15 drachms of powder 5 balls	No effect.

The fowling piece was put to the following proofs:—

First proof......	10¾ drachms of powder 2 wads 1 round ball of 24 to the pound	No effect.
Second proof...	Same powder 2 wads 2 round balls	No effect.

It was then determined to burst this barrel by putting in a proof charge and two balls, then cramming the muzzle of the barrel to the extent of two inches with moist clay. The result was, that the barrel burst at the bottom of the clay, only tearing off about two inches of its length, and showing no other signs of injury. A similar barrel, proved at Birmingham, only slightly bulged, with twenty drachms of powder and three balls.

Among the party present were Mr. Patchett and Mr. Bond, the eminent gunmakers, Major, General Willoughby, C.B., Colonel Sale, J. Thornton, Esq., R. Pownsett, Mr. G. Latham Browne, Lieutenant Hardinge Browne, R.A., Mr. J. J. Burnett, and the patentees. Several specimens were also exhibited, showing the applicability of this process to drawing hollow tubes in iron or steel, of any shape, and almost any reasonable length. At present we understand it has not been applied to tubes of more than 1⅜-in. diameter, or to a length exceeding 30 ft. Its extension to larger tubes is evidently a mere question of mechanical power. The patentees estimate that, by the adoption of their process, the cost of iron gun barrels will be reduced to one third, and that a cast steel barrel can be supplied at the present cost of an iron one.—*Standard.*

The Paris journals announce the decease at Trouville, where he generally resided, of M. Mosin, marine painter. He was in his 56th year.

BOBY'S IMPROVED LAND ROLLER.

FIG. 1.

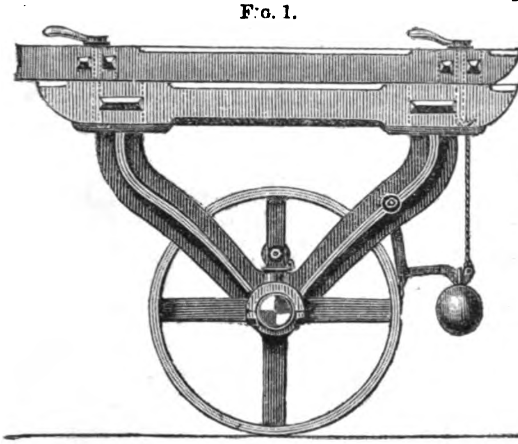


FIG. 2.

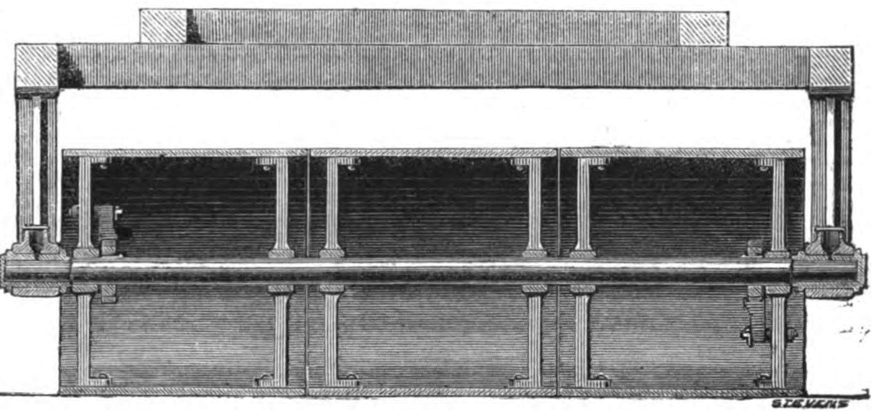
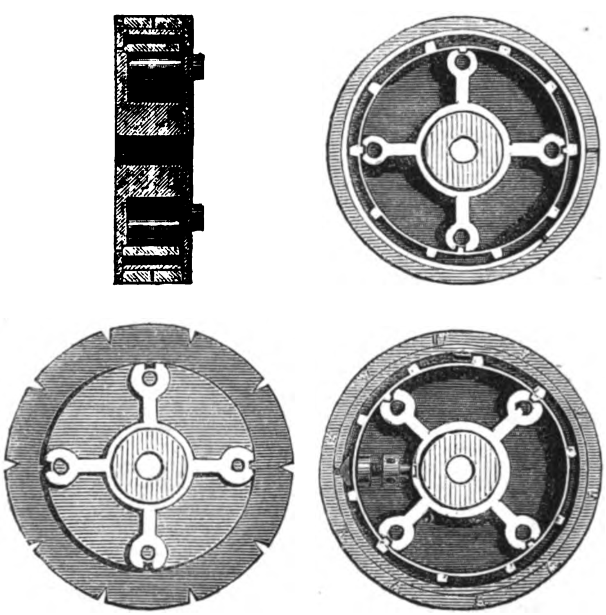


BOBY'S IMPROVED LAND ROLLER.

MR. R. BOBY, of Bury St. Edmund's, so well known for his corn screen, has just obtained a patent for an improved roller for crushing land. The invention relates to a novel mode of mounting and arranging the several parts, so that the friction of the working parts, and the power required to draw the implements over the land, may be reduced. The above engravings illustrate the apparatus. Fig 1. is an end elevation; and Fig. 2 a longitudinal section of the same.

The axle on which the rollers or pressing wheels are mounted, turns in properly lubricated bearings or grease boxes, so that it may rotate therein with as little friction as possible. If the roller or clod crusher be composed of two or more parts, or pressing surfaces, one or more of the parts of wheels may, if desired, be permanently or temporarily attached to the axletree or spindle by means of ratchet wheels, wedges, or other analogous contrivances. The axle or spindle will be obliged to turn in its bearings, but the ratchet attachments of the rollers will allow the latter, when passing round curves, or when the implement is being turned round at the end of the field, to turn back or rotate on the spindle. By this arrangement the friction of the working parts will be reduced to a minimum, and the power required for drawing the implement over the land will be materially lessened. The crosses or arms of the rollers are provided with bushes or pairs of bearings, so that should any part be worn away, the damaged part may be removed and replaced by a sound one.

SCOVILLE'S PATENT PISTONS FOR ENGINES.



SCOVILLE'S PATENT PISTONS FOR ENGINES.

THE accompanying engravings show an improvement in pistons for steam-engines, recently patented by Mr. G. Scoville, of Furnival's Inn.

The object of this invention is to simplify and perfect the use and application of metallic packing for pistons of steam-engines, and to dispense with the use of springs or other mechanical contrivances for adjusting the regulating such packing. This object is effected by substituting steam by means of a simple mechanical arrangement for the springs or equivalent mechanical contrivances usually employed for the purpose. Instead of the rings in common use in locomotive pistons, which are ordinarily made of brass and Babbitt metal, and are consequently very expensive, cast-iron rings may be used. As the rings in common use are so well known, it will only be necessary to say that in locomotive engines ordinarily the two outside rings are made alike about three-quarters of an inch thick, and wide enough so that the two when in position will fill the space between the flange of the piston head and the follower, and work freely. Each ring is severed or cut across diagonally, so as to allow expansion when pressed upon from the inside. The inside ring in the piston of the ordinary locomotive engine is usually one quarter of an inch thick, and of the same width as both the outside rings, cut open in the same manner, and when in position between the flange of the piston head and the follower, rests on the inside surface of the outside rings, the openings in all the rings being at different places, so as to break joints. Instead of springs or any other mechanical contrivance for pressing the rings out against the cylinder a fourth ring of cast iron or other metal is employed, and may be termed a valve ring. This ring is placed within the inside ring; the width of this valve ring when finished is a very little less than the distance between the flange of the piston head and the follower, say one thirty-second of an inch less, and it is turned off on the edges in a lathe. This valve ring is made with bosses on the outside, and large enough, so that when in position the bosses will touch the inside ring. The object of these bosses is to strengthen the valve ring without making it heavy, and to form spaces between the valve ring and the inside ring, so as to allow the free action of the steam on the inside ring, and at the same time to support the valve ring, while resting on the inside, ring holes are made in the flange ring for the admission of steam into the spaces behind the packing rings. It will be obvious that as the steam is let into one end of the cylinder it will pass through the small holes in the flange of the piston head or follower, opening against the bosses on the valve ring, and pressing the valve ring over against the holes on the opposite side, it will thus close those holes and be prevented from escaping or blowing through; the pressure of the steam must consequently be exerted on the inside ring, and thereby be brought to bear upon the outside rings and cause them to expand against the side of the cylinder, and forming a perfectly fitting piston. When the piston is forced to the other end of the cylinder, and the steam is let in at that end, the action of the valve ring is reversed, and the pressure of the steam on the rings is exerted from the other side of the piston head. Thus the valve ring, in its operation with the holes above described through the piston flange and follower, is simply a valve or series of valves for the purpose of admitting steam into the piston head, and is made in the form aforesaid so as to present a considerable surface against the flange of the piston head and the follower, to prevent wear. The valve ring may be made with a flange on each end of the same width as the combined thickness of the ring and boss, with holes through the ring between the bosses to allow the free passage of steam to and against the inside ring. The advantages of this invention herein described consist in its being easily and cheaply applied to the packing of pistons in steam-engines already made in the ordinary way with springs, and in securing a uniform and even pressure upon the rings that form the packing of the piston, causing them to wear smoothly and evenly, not cutting the cylinders, and consequently lasting much longer than the metallic packing in ordinary use. It is also durable and not liable to get out of order, and is peculiarly valuable in locomotive engines, as when running down gradients or whenever the steam is shut off; the piston works freely and without friction, as is not the case when the packing is set out by any other means than the steam itself.

THE COMPARATIVE ADVANTAGES OF FIXED AND MOVEABLE STEAM-POWER, AND OF SINGLE OR DOUBLE DRESSING THRASHING MACHINES.

By R. Vallentine.

PRIZE ESSAY.

The comparative advantages of fixed or moveable steam-power obviously depend very much upon a variety of special circumstances. On large scattered farms, having several sets of out-buildings at which straw would be required, a portable engine will of course be most suitable, if not indispensably necessary; and where steam-cultivation is also to be carried on, there would be a double advantage in the power being moveable. On some large farms, however, having central buildings, in which a great deal of thrashing is done besides grinding, chaff-cutting, &c., so as nearly to occupy an engine, a fixed power will prove most economical, even although steam cultivation be carried on by a separate moveable power. But generally, where a portable engine can be made fully available for both thrashing and cultivation, the cost of both operations is very much reduced by dividing between them the first outlay and percentage of maintenance, instead of these being all charged to either the corn thrashed or the land cultivated. Instances are numerous where in practice one moveable engine is thus found sufficient for every purpose required. Again, there are many farms provided with two sets of buildings which require a good deal of thrashing at each. In such cases, if letting out for hire be not contemplated, I think a moveable engine with fixed thrashing machines preferable to one moveable machine; since besides other important advantages, to be described afterwards, two fixed thrashing parts cost no more than one portable machine, whilst the cost of maintenance is much less.

Personal experience with every variety of steam thrashing machine falls to the lot of few, if to any; although personal experience of the use of some machines, and the observation of others, are possible enough. From all I have seen, and the chief of what I have heard, double-dressing machines, or rather those which are intended for dressing the corn so as to prepare it at once for market, do not succeed. There are times when the corn to be thrashed is of very uniform quality and condition, when a very fair and well-dressed sample may be obtained by blowing out a great deal of offal and light corn, with some that is good; but, as a rule, the attempt to turn out the corn ready for market from the thrashing machine is attended with loss. With the best engine-driver and the best feeder, there are times when the machinery goes slower than is desirable for driving all the light corn and short straws out of the bulk: it is then impossible to have the corn in marketable order. Again, the tops and bottoms of stacks are frequently more damp than the middle; the quality of the corn in the stack also frequently varies. Under such circumstances it is impossible to obtain an average sample unless the whole is turned into a heap, and mixed by subsequent dressing or dressings. There is also an objection to the complexity of most of those machines which are professedly intended to dress and sack up the corn for market. There is always a liability to something going wrong, and however slight the damage or disorder which takes place, the waste of time and labour incidental to frequent short stoppages may be greater than that caused by a long interruption at distant intervals. So liable, indeed, are some of those complicated machines to get out of order somewhere or other, that in one instance I have known a whole winter to pass over, including many days of thrashing, without the work being kept on regularly for even one day free from some vexatious stoppage! Few machines are so very bad as this; but many give great trouble. Moveable dressing-machines are also less serviceable than single blowers, on account of their increased weight. Some compact six horse-power single-dressing thrashing machines weigh only 45 cwt., whilst some of those huge do-every-thing machines weigh $3\frac{1}{2}$ tons. There are people to be found who stick so pertinaceously to any favourite of their adoption, that they will contend that steam power is cheaper than hand labour for dressing corn, or, indeed, any purpose. This corn-dressing is, however, rather a nice operation, and requires more care and discrimination than mere power. A double-dressing machine, as a fixture, is much to be preferred to portable machines, although it is only rarely that an equal sample can be obtained, especially of wheat, from the machine, without a due mixture of the whole bulk.

A fixed thrashing-machine placed on a loft 8 ft. high, admits of double-dressing the corn, without the necessity of elevators, revolving screen, or such like complicated machinery; and, although a further hand-dressing may still be necessary, this is much easier done well than when only a single dressing has been effected by power, or a mere separation of the chaff and corn made.

On the great bulk of arable farms, where steam cultivation is not in progress or contemplated, a fixed steam-engine is comparatively much better than a moveable power. First, the cost of a fixture is less than that of a moveable engine, in the proportion of 3 to 4, according to the prices of the leading makers. A fixed engine costs about £25 per horse-power, whilst a portable engine costs about £33. The price of a fixed thrashing-machine, as compared with a moveable one, is as 1 to 2; fixed thrashing-machines being made by several firms at £8 per horse-power, whilst portable machines usually cost from £16 to £18 per horse-power The difference, therefore, in purchasing a fixed or moveable engine, say of 6 or 8 horse-power, would stand about thus:—

Fixed Engine and Machine.

6 horse-power engine, at £25	£150	0
Ditto machine, at £8	48	0
	£198	0

Portable Engine, &c.

Engine, 6 horse-power, at £33	£198	0
Machine, at £16	96	0
	£294	0
Deduct cost of fixed engine, &c.	198	0
Extra cost of portable engine, &c.	£96	0

Thus, in round numbers, there is a difference of £100 when the moveable engine, &c., is of 6 horse-power; and the same relative costs hold good for any higher power, although the price per horse-power is less as the size and power are increased. For simplicity of calculation, I shall take the above statement of a 6 horse-power engine for estimating the cost of maintenance. Two years ago I put up a fixed engine on this farm, the working of which, &c., I shall by and by describe. After thrashing out two crops of about 120 acres each, the engine seems as good as new, and has cost nothing whatever for repairs of any kind. I allude to this merely to show that estimates on the cost of maintenance of engines generally cannot be fairly based on personal experience alone. My calculations will, therefore, refer to a number of engines, both fixed and portable, which have been working in various parts of the country for from ten to twenty years. Some of the fixed engines have worked for twenty years, and the portable engines from eight to twelve years. Fixed engines generally require a new boiler every ten or fifteen years, with a small outlay for very moderate repairs and new brasses. The average cost of maintenance for several fixed engines, which have worked about six months in the year, has been about 10 per cent. Portable engines are, however, well known to be extremely costly articles for repairs, and those who have worked them six years and upwards tell me that the cost of maintenance is fully 20 per cent. This seems a high allowance, certainly; but then it is necessary to remember that engines which travel about the country, and are in nearly constant work, with rough usage, must suffer more than would be the case with an engine confined to one farm, worked less, and taken more care of. With portable engines, there is seldom much cost for repairs for a few years; but, as the saying is, "when once they begin to go, there is no end to their wants." From their construction, however much care may be taken of them, they are sure to require more repairs than fixtures. The fire-box, tubes, brasses, &c., wear out sooner, besides being more costly for repairs than the more solid parts of a fixed engine. The estimate of 20 per cent. for maintenance certainly seems a high one; but as this is the sum stated as barely sufficient by those who have had much experience in the matter, it may be fairly adopted as a basis of calculation. Let us, then, put together the prime cost and the cost of maintenance of the fixed engine, and contrast that sum with the cost of the moveable machinery, so as to show at one glance the comparison between the two:—

Fixed Machinery.

6-horse power engine and machine, say	£200	0
Cost of maintenance at 10 per cent.	20	0
	£220	0

Moveable Machinery.

Engine and machine, say	£300	0
Cost of maintenance at 20 per cent.	60	0
	£360	0

According to this statement, the relative first cost of a fixed and moveable engine is as 2 to 3, and the relative cost of maintenance as 1 to 3, which shows the great comparative economy of fixed over moveable engines where the one can be substituted for the other. Indeed, so great is the difference that the cost of thrashing on most farms would be more than doubled per year by using a moveable instead of a fixed engine. Those who let out machines for hire do not on an average make large profits, although the number of quarters of wheat thrashed in a year necessarily much exceeds the produce of a single farm. This great amount of work, however, must cause a proportionately greater amount of tear and wear than would arise on any ordinary farm. I think, therefore, that such a calculation as 20 per cent. for repairs and depreciation of value must be too much if applied to the work on one farm, unless the engine was kept almost constantly at work in grinding and other tasks besides thrashing.

On any farm where as much as from 300 to 600 quarters of corn is grown, the erection of a fixed engine would be far more economical than hiring. My own farm produces generally from 400 to 600 quarters annually; for several years I hired a 6 horse-power engine and machine to thrash at 1s. per quarter. The owner of the machine found an engineer and feeder, who had to be boarded during the thrashing. The engine, which had to be brought an average distance of four miles, weighed with the machine $5\frac{1}{2}$ tons, and required six horses to bring it out of fields and along indifferent roads. The machine sometimes thrashed 40 quarters of reaped wheat a-day, but seldom more than 20 quarters of strong bagged or mown wheat; of barley, from 20 to 30 quarters, and of oats from 30 to 50 quarters, per day. There were, however, days lost and parts of days, which materially reduced the average of a day's thrashing throughout the season. So much was this the case, that reckoning every day when the fire was lighted, the average of corn of all kinds, taken together, thrashed in 26 days, was only 20 quarters. The cost of labour, when thrashing by a moveable machine for several days together, was as follows:—

	£	s.	d.
1 engineer, board, beer, and lodging	0	2	3
1 feeder " "	0	2	3
2 men on stack, wages 2s., beer 3d., at 2s. 3d.	0	4	6
2 men untying or forking loose corn, at 2s. 3d.	0	4	6
1 man removing thrashed corn	0	2	3
5 men stacking straw, at 2s. 3d.	0	11	3
3 boys (1 carrying water for engine, 1 for chaff, 1 for cavings), wages 9d., beer 3d.	0	3	0
15	£1	10	0

Where elevators are used for the straw, three men may be dispensed with. A further saving of three hands—one on the stack, another untying, and a lad employed with chaff and cavings

—might possibly be effected; but practically, if the work is to be finished in proper style, as many as fifteen hands are required, and it is quite as usual to find that more, rather than fewer, are employed.

Cost of Hired Machine per Day and per Quarter.

	£	s.	d.
Hire of machine for 20 quarters, at 1s....	1	0	0
15 men and boys, at an average of 2s. per day, including beer	1	10	0
Coal and carriage	0	10	0
	£3	0	0

This is just 3s. per quarter, leaving out of account the cost of horses and men in bringing the machine an average distance of four miles, for four days' work or so at a time. The usual calculation, indeed, is that a hired machine costs about £3 10s., when every expense is included. I shall, however, abide by £3 as nearest to my experience. The cost of thrashing 500 quarters of corn, at 3s. per quarter, amounts to £75. In addition to this cost, there was a great deal of extra horse and manual labour incurred by bringing in the straw and cavings to the yard throughout the winter. Thatching was necessary to preserve the straw from getting wet, and with every precaution, there was always much litter and waste in the stackyard which could not be estimated. To clear up the *debris* of the various thrashings, the services of a man with a horse and cart were always necessary for some days, which I have estimated at £5 a-year to the debit of thrashing out of doors. The comparative waste of thrashing in and out of doors cannot be exactly ascertained; but my opinion is that more corn is wasted and spoiled by out-door than in-door thrashing. If you are caught by rain when taking in to the barn, the stack can be more quickly covered up than when not only that but the machine and some space around it require protection. When a great number of hands are employed with a portable machine, there is also a temptation to keep on thrashing, although it be not quite fine, or if actually stopped, to resume work quickly again, when wet runs about the stack and has damped the thrashing-machine. He who hires a machine is never certain when he may get it to a day, or sometimes to a week. It may happen that the very day the machine is set down to work, it begins to rain: the machine and hands to work it have come, and if there is any chance of getting on at all, it is the ordinary course to begin. Any one who has a fixed machine may generally choose a promising day for taking in, so as to incur much less liability to interruption than when thrashing for days together with a hired machine.

The natural place for straw is the yard. When a fixture is used, the corn in the straw, together with all the chaff and cavings in one bulk, is brought to the barn in fewer loads than the straw alone, after being thrashed, would make: moreover, two loads of sheaves may be loaded in the same time as one load of loose straw. When the straw is got into the barn adjoining the yards, it is readily carried about by a fork, and that regularly as wanted. When carts are used for conveying the straw, it is very frequently thrown down too thick, and at too long intervals. With a fixed machine, the chaff and cavings are deposited in their proper places, without either a waste of material or labour at all equivalent to that incurred by thrashing in the open air. The fodder for cattle is much more safe from wet and more handy in the barn than out of doors. Even though cattle-men be very careful, still wet must penetrate the stack at times when a cut is made, and damage to the straw must ensue, in addition to waste of labour and a litter in the stackyard. I cannot find that a fixed engine and a fixed thrashing machine have any drawbacks comparable to those attendant on moveable machines. At first sight thrashing in the field appears to be a quick process, which saves the trouble of moving the unthrashed corn; but, before all is done, more labour has been incurred. I once thrashed out 20 acres of barley in the field, and left the straw, chaff, and cavings, according to the usual course, to be brought home at leisure. Having no waggons, a man with a horse and cart was employed nearly all the winter for days together, to clear up; but, after all, he only made, as it were, a small hole in a large mountain, which required for its removal a great many carts for several days. The odd man in winter went more times for about perhaps 2 cwt. of chaff at a load than would have been sufficient to have brought in the whole of the unthrashed corn.

The past two winters I have only required a man for a few days altogether to clear up the refuse thatch in the stackyard. When taken in and thrashing, I now require for a regular full day's thrashing six men and two boys—one man and boy at the stack, one stout lad emptying carts, one man untying sheaves, one feeder, one man in straw-barn, one engineer, and one boy shovelling corn away from dressing machine. The engineer or the man who attends to the straw can generally for a minute or two at intervals look to the corn-barn. As, however, two men and a boy would be required to cart in the straw to the yards, if thrashed out of doors, that number of hands may fairly be kept out of the account of cost of thrashing. The number of hands required when the corn is in, then, amounts to four men and one boy, unless, which rarely happens, more than one day's thrashing takes place at a time, when two men are required at the straw. When thrashing out of doors with a hired machine, I found by experience that, including interruptions, the corn thrashed did not average more than 20 quarters per day, but for thrashing in-doors an average of 25 quarters may very fairly be taken; because, firstly, you will be more secure from such interruptions; and secondly, because a broken day, instead of being a serious hindrance to the work of the farm, may often be an accomodation, and provide work under cover, for hands that would otherwise not find profitable employment:—

Estimate of Cost of Fixed Engine for thrashing per Day and per Quarter, allowing 25 quarters per day's thrashing on 20 days a year.

	£	s.	d.
Interest and depreciation on £200, at 10 per cent., divided among 20 days	1	0	0
Interest on outlay of £100 for buildings for engine and machine, at 7 per cent., £7, divided by 20 days	0	7	0
3 men, at 2s.; 1 man, at 2s. 6d.; 1 boy, 6d ...	0	9	0
6 cwt. coal, with carriage	0	7	0
Oil	0	0	6
	£2	3	6

Total cost, £2 3s. 6d., which, divided by 25, gives 1s. 9d. per quarter.

When thrashing more than a day at a time, the straw requires stacking, and of course more hands to attend to it: two hands untying may also be required in case of very short sheaves, or that loose corn may be properly shaken up. Seven hands are the fewest who can work the machine and take in and thrash at the same time. Four hands only are required to thrash when sufficient corn is in the barn for half a day's thrashing; two hands can take in in a day enough for half a day's thrashing; four hands are required to fill the barn for a whole day's thrashing when the machine is not going. With a fixture all this may be varied, according to circumstances. In wet days, or parts of days, a great deal of thrashing may be done when the labourers could be occupied about nothing else.

By the hired machine the cost per quarter was about 3s., by the fixed engine about 1s. 9d. per quarter, being a saving of £31 5s. on 500 quarters. In this account, be it remarked, the increased labour of cleaning up the stackyard, which is now saved, is not taken into account. An additional advantage is that the straw, chaff, and cavings are kept dry and convenient for use, and though no exact price can be put upon these, I certainly do attach a considerable value to them. My horses have no hay during some months of winter, and eat up chaff, &c., very readily when given fresh. It is certainly anything but economical either of labour or material to waste chaff, and then cut straw to supply its place. The great bulk of practical farmers admit that the chaff of any kind of corn is more nutritious than the straw. Chemical analysis testifies to the same: then why waste chaff as of no use, when ready to hand without cutting? and why waste cavings, which are the most palatable and nutritious of fodder?

The fact is, that where there is a fixed machine a few hands can frequently be spared without inconvenience from other labour for thrashing, and sometimes a wet day may be turned to account when nothing else could be done. Two hands with an odd horse may often be spared to take in the matter of 12 or 20 loads of sheaves in a day, which can afterwards be thrashed on any morning or afternoon. When a fixed machine is used, the time of many hands cannot be wasted, as is frequently the case when the locomotive is changed from stack to stack. I like to have long stacks made in short joints for the convenience of taking in one or two parts, as it may happen, in a day. About fifteen or twenty cart-loads in a round stack make it a convenient stint for short winter days. My machine thrashes far more than twenty-five quarters a day, when worked all day; but not wishing to over-estimate, I have taken this as an average quantity. In thrashing oats, half a day's work often suffices to nearly fill the barn with straw. The expense of raising the steam—about 1s.—is of no account compared with the importance of getting the thrashing done when hands are convenient and straw required. I only pay the engineer extra wages when he drives the engine: 6d. a day extra is all the allowance, which amounts to very little in the course of the year; but still it seems to be a sufficient inducement to keep the engine clean and in good order, and to remain half an hour or so after the other workmen leave. Many people pay an engineer higher wages per week throughout the year. This is doubtful policy, and is certainly not economical where only a few weeks' work are required in the year.

My buildings are well placed with reference to the yards and stacks. When once the straw is in the barn, it is easily moved to the various places where required. My engine and machine of 6-horse power cost less than £200 when everything was included. The thrashing-machine, including a shaft which runs from the engine-house into the corn-barn, cost under £40. The maker lived near, and was at no cost for travelling expenses or carriage of materials, &c. Attached to the thrashing machine is one blower, similar to those generally belonging to portable machines: then from the shaft which extends into the corn-barn another common winnowing machine is driven by a strap. This machine (which only requires one small bolt to fasten it to the floor) is fed by the corn running down a spout, after being separated by the first blower from the chaff. This arrangement is so simple that there is little chance of anything getting out of order, and generally the corn is very well cleared, but not sufficiently so to be ready for market. Oats for home use, or barley for grinding, require no subsequent dressing. The lower dressing machine, which is worked by the engine when thrashing, is detached in a moment for dressing by hand.

A circular tank, 9 ft. deep and 9 ft. in diameter, to receive the soft water from the roofs of the buildings to supply the engine, was dug and bricked round with common mortar for about £6. The tank holds 4,000 gallons, or would do so if full; but a waste-drain, laid nearly a foot below the surface, as is desirable, of course diminishes its capacity. When full, the tank contains enough water to keep the engine going from 12 to 15 days. Practically it has never been nearly empty, as a good fall of rain for 24 hours makes it run over. Soft water is far preferable to common spring water in many respects, and a supply is generally thus more cheaply obtained than by sinking a well. I have already estimated the cost of preparing common farm buildings for the reception of fixed thrashing machinery at £100; such was my own experience.

The following are the details of the additions and alterations, as made by the landlord:—

Details of Buildings for Engine and Thrashing-machine.

	£	s.	d.
Chimney 40 ft. high, about 7,000 bricks, and labour	20	0	0

KENNEDY'S IMPROVED PROPELLERS FOR SHIPS.

Fig. 1.

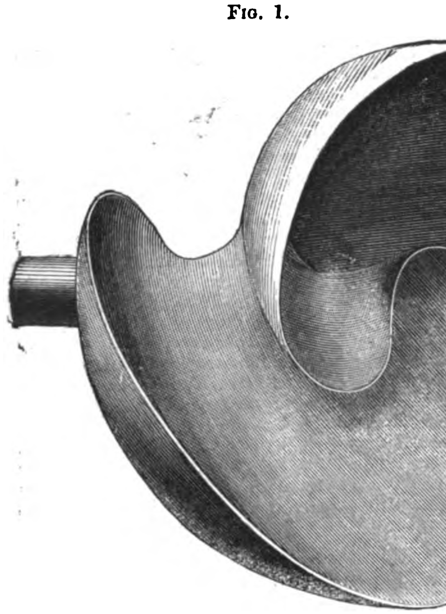


Fig. 2.

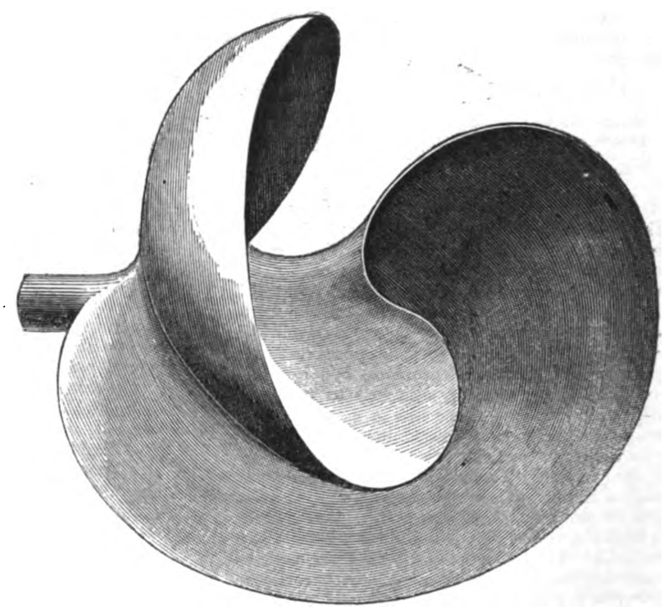

Engine-house, 13 ft. by 15, including fixing of boiler outside	30	0	0
Corn barn-floor, 21 by 11 ft. — 231 square ft. at 6d.	5	15	6
Loft where machine is placed, &c., 21 by 18 ft. —378 ft. at 9d..	14	3	6
Chaff-house floor, below, 21 by 7 ft. — 147 ft. at 6d.	3	13	6
Wooden partition between corn-barn and chaff, 21 by 8 ft. — 168 ft. at 6d.	4	4	0
Brick partition between corn-barn and unthrashed-corn department, 18 by 8 ft. — 144 ft., at 6d.	3	12	0
Building one brick thick, inside barn, on two sides, to receive the bearing of the battens for loft above, instead of beams, two sides, 21 by 8 ft. each — 336 square ft. at 6d.	8	8	0
Soft-water tank, 9 ft. diameter, 9 ft. deep; digging out and building with bricks and mortar, at 4s. per square yard (capacity of tank about 4,000 gallons)	6	0	0
Doors, window in corn-barn, drains, &c., about	5	0	0
	£100	16	6

I likewise had a granary built over the engine-house 13 by 15 ft., at a cost of about £24 for walls, floor, door, and window, exclusive of the roof, which would of course be required for engine-house, without such addition. This item I have not included in my estimate, because it is not necessarily connected with fixed thrashing-machinery. An engine-house, made as a lean-to, of one brick thick, would cost only about £20., roof included. A corn-barn, as above, 21 by 11 ft., would contain, when full, about 220 quarters of corn; but practically 50 or 60 quarters is all that can conveniently be held for dressing over and keeping the offal, &c., apart from the dressed and undressed corn.

In conclusion, I would repeat, that where a moveable engine could be employed in ploughing as well as in thrashing, there are great temptations to give it the preference; but otherwise the fixed engine is more desirable, since, whether my calculations are nearly correct or not, there can be no doubt that it is far more economical. At the same time when I ordered my fixed machinery, a friend, who had some outlying farm premises got a moveable engine, and found it not only more costly, but more troublesome to manage. Where such outbuildings exist too distant to be supplied with straw from the chief homestead, I think a fixed thrashing-machine would prove the most economical, even though moveable power should be hired to drive it. A fixed engine might at the same time do the chief part of the work at the home farm.

Having now endeavoured to discuss, as fairly as possible, the various points connected with this subject, I must leave others to draw their own conclusions whether a moveable or fixed engine will best suit their individual purpose.

Burcott Lodge, Leighton Buzzard.

KENNEDY'S IMPROVED PROPELLERS FOR SHIPS.

Mr. J. Kennedy, shipbuilder, of Whitehaven, Cumberland, who has lately paid considerable attention to the construction of ships, more particularly suitable for naval warfare, has invented and obtained letters patent for a screw or propeller which can be protected from an enemy's shot by means of an armour-plated shield, and from becoming fouled by wreck or other floating impediments. The invention consists in fixing, to a suitable axis, two or more blades of such a form as to enclose the water within their grasp when revolving. The shape of the blades somewhat resembles the form of the tail of a fish; the pitch can be altered by making the blades more or less deep or long.

Figures 1, 2, and 3, of the accompanying engravings are perspective views of three of these propellers, each view showing a propeller of different pitch. Figure 4 shows a propeller applied to the stern of a ship. The propeller shaft is there supported, and free to revolve in two bearings. The propellers for small vessels consist of blades, made of several pieces of iron, attached to an axis or shaft; but when of considerable size, are made of plates of metal, either steel or iron, rivetted upon ribs, with T, or angle iron, at the edges.

THE BED OF THE ATLANTIC OCEAN.

By Professor W. King.

The following "supplementary note" of Professor King, of Queen's College, Galway, is in continuation of that gentleman's report to the Atlantic Telegraph Company, published in this magazine on the 21st inst.:—

Mr. Hoskyn preserved specimens of Deep Sea Soundings in bottles containing spirits, by which means they have been prevented from drying, and have retained their original consistency. Orbulo-globigerinous mud thus preserved has quite the appearance of a thickish batter paste. To what depth below its surface the deposit continues in a pasty condition, has not yet been ascertained. The "bull-dog machine," so successfully used on board H.M.S. "Porcupine," brought up large quantities of it; we may therefore conclude that the deposit was penetrated to the depth of a few inches. Further, if we take into consideration the enormous vertical pressure of the ocean in deep places, it is difficult to conceive otherwise than that water would be forced to a considerable depth into the permeable mud, forming the two-mile deep "telegraph plateau." Under these conditions, we may fairly assume that at least its surface mass is highly charged with water, and consequently so soft and oozy that a body like a telegraph cable could not remain long on it without being covered up.

The mud, consisting as it does of living and dead foraminifera and their comminuted *debris*, is clearly an organic deposit. The rate at which it is formed will therefore depend on the rate of reproduction of these organisms, all other circumstances being favourable. Although little is known regarding the subject just mentioned, still we may form some idea of the rate at which foraminifera increase or multiply by a reference to facts supplied by other living objects. It is well known that many of the lower groups of animals are enormously reproductive. Numerous cases might be adduced, but it will be sufficient for my purpose simply to notice a group in which calcareous matter is an abundant constituent. Darwin, on the authority of Lieut. Willstead, R.N., cites the case of a ship stationed in the Persian Gulf, the bottom of which became encrusted with a layer of coral 2 ft. thick in 20 months. He likewise notices some experiments made by Dr. Allan on the coast of Madagascar, from which it was ascertained that portions of coral weighing 10 lb. increased 4 ft. in height and several feet in length during the short space of 6 or 7 months (*vide* Darwin's "Coral Reefs," p. 77 and 78). These cases may be accepted as good analogical proofs in favour of the belief that foraminifera, the lowest group of animals known, multiply to a surprising extent.

While investigating this subject, however, we must not overlook matter of some importance. Both corals and foraminifera shells are formed of lime derived from certain, if not all, of the calcareous solutions occurring in the ocean, the principal being sulphate of lime (4·617 per cent.) and chloride of calcium (3·657 per cent.), that is, proportional to other associated mineral ingredients. How these two compounds are in the first place derived, as appears to be the case, from another calcareous compound, viz., bi-carbonate of lime, common to the water, which rivers discharge into the ocean; or how they are afterwards decomposed by the vital agency of coral forming zoophytes and foraminifera, and next converted into the carbonate of lime of their skeletons or coverings, are subjects beyond my present purpose. The question for consideration is, are calcareous solutions as copiously supplied to the Atlantic, for its foraminifera, as they are to the tropical seas for the uses of coral-forming zoophytes? I see no reason to doubt the affirmative, as the per centages above given are deduced from analyses, made by Bybra, of

KENNEDY'S IMPROVED PROPELLERS FOR SHIPS.

FIG. 3.

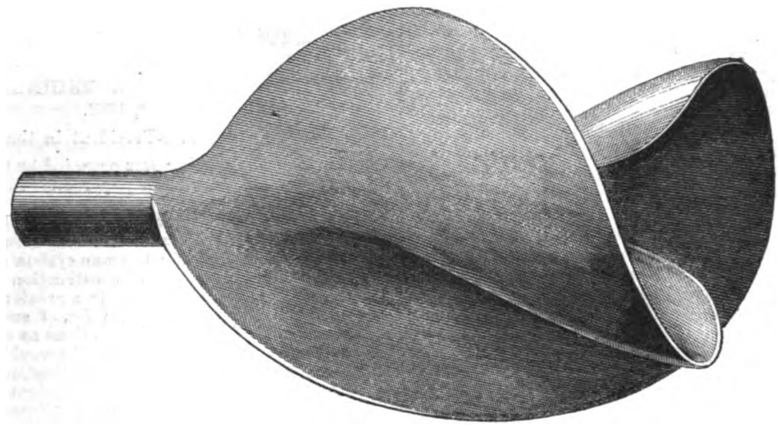

FIG. 4.

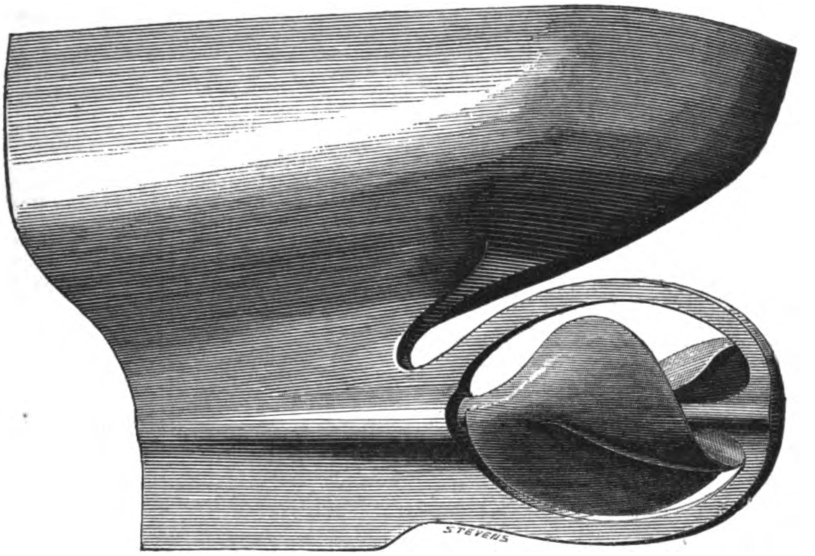

waters from the Pacific, Atlantic, and German Oceans.

It may also be observed that the balance of Nature requires us to believe that the foraminiferous life of the deep Atlantic is quite equal to the supply of calcareous matter. Thus, considering that rivers are every moment conveying enormous quantities of lime from the land into the sea, and that oceanic currents are widely diffusing it over the Atlantic, we may conclude that foraminiferous organisms, everywhere occurring on its deep sea bed, are appropriating this calcareous matter as rapidly as it is supplied. They evidently play the same important part in our seas as the coral forming zoophytes in warmer latitudes; and although the latter are labouring in shallower depths, and building up the more striking atolls and fringing reefs, the latter are nevertheless working quite as efficiently in the abysses of the Atlantic, and forming an enormously wide spread calcareous deposit. Ages on ages will be consumed before this deposit can attain the thickness of some of our limestone masses; but assuredly it will be materially increased during the short space of a human life.

In conclusion, reflecting on all the considerations which have been noticed, I feel my conviction strongly supported that a telegraph cable, if laid down on the orbulo-globigerinous bottom of the Atlantic, will, after the lapse of a few years, become sufficiently covered up to be protected from any ordinary dangers.

THE NEW ERICSSON BATTERY.

ON the 15th, the Ericsson battery, "Passaic," made her final trial trip, when her great guns were tried. The following is a report of the experiments:—

Firing commenced at half-past 1. The first shot struck about 300 yards from the vessel, in the water, glanced off, and flew into the bosom of the Palisades. Nothing broke—the turret was there, as strong and solid as a rock. The concussion was not felt any more than the captain of a 32-pounder feels it on board a frigate. The first fire resulted in no smoke to speak of, no inconvenient concussion, and the complete success of a grand idea. The first charge consisted of 20 lb. of powder, and a hollow shot (330 lb.), fired out of the 16-inch gun. It recoiled 17 inches. The second shot was fired out of the 15-inch gun, there being really no need of discharging the 11-inch. The first shot having proved the practicability of the principle, the entire charge of 35 lb. of powder was now put in. Notwithstanding the success of the experimental fire, the timid ones still kept in the background. Captain Drayton pulled the trigger. Once more the echoes of the Palisades rang out. The recoil and smoke were reported "insignificant," and the shot — a hollow one — buried itself again in the beach. Cheers were loudly given for the "Passaic." The noise is only troublesome outside the turret, on deck, where no one has any business to be. The recoil was a few inches greater than at first, owing to the compressers not being properly tightened. At the third shot the compressors were righted, and there was even less recoil than at first. A full 35 lb. charge was put in, and the 330 lb. hollow shot. The ball struck the water as before, there being no desire to elevate the gun, or to test any but the one great principle. The facts established by the experiment are as follows:—First, a gun may be fired inside a turret. Second, in order to appreciate the nature of the second result, it should be known that the Armstrong guns in England have been condemned for use on shipboard, chiefly because a sufficient number of men could not be placed in the turret to work them; 25 failed to do it satisfactorily, and the Armstrong gun weighs but 14 tons. On Saturday, four men worked a 15-inch gun, which weighs 20 tons. Next week Mr. Whitney will put a 15,000 lb. gun on board the "Koekuk," which will require 20 men, while the 42,600 lb. gun of the "Passaic" is moved by four. Third, the third result is a very important one. It is the immobility of the "Passaic." Waves break on the iron margin of the craft and splash in harmless foam about the deck. They have no hull to strike—no high bulwarks; even the turret presents an angle at every side. So much for the results. The following is a tabular recapitulation of the experiments:—

	Ball weighed.	Charge of Powder.	Recoil.
First shot ...	330 lb. (hollow)	20 lb.	17 in.
Second shot	330 lb. (hollow)	35 lb.	3 ft. 10 in.
Third shot...	330 lb.	35 lb.	2 ft. 8 in.

UNBRANNING OF WHEAT.

IN the report on the alleged grievances of the journeymen bakers, made by Mr. H. Seymour Tremenheere, to the Secretary of State for the Home Department, a process of unbranning wheat is described, which seems likely to exercise an important bearing on the supply of food. Messrs. Hadley, of the City Flour-mills, stated to Mr. Tremenheere as follows:—

"We have been making experiments for some time on the mode of unbranning wheat, invented by Mr. Bentz about the year 1846, in America, and subsequently patented. The object of this process is to separate the outer cuticle, which is wholly innutritious, from an interior section of the wheat-berry, which contains mostly nitrogenous matter, and which has hitherto been lost as human food.

"There are two leading advantages in this process. First, the cleanliness of the flour produced. In grinding by the ordinary process it is impossible to render the flour entirely free from dust and dirt. After putting the wheat through two or three processes of cleaning in the common way, there will still be some dirt remaining in it. All flour always contains more or less of this dust. There is also a portion of the beard of the wheat, a kind of fibrous appendage, which is always ground up with it; no process hitherto known has been able to get rid of it.

"By Mr. Benty's process, as the exterior cuticle is entirely removed previously to grinding, the flour is necessarily perfectly clean, and free both from dust and this fibrous down.

"Secondly, by the ordinary mode of grinding, the result obtained is 76 per cent. of flour for human use. By the new process we find, after a series of very careful experiments, extending over several months, that we obtain about 86 per cent. of the whole berry available to make bread.

"The money value of this increase of 10 per cent. is subject to a deduction of about one-half in consideration of the lessened quantity of offal, the value of which we may take at half of that of the flour if used as human food. The offal is used for many purposes, which give it a value larger than would at first sight be conjectured.

"In addition to this net increase of 5 per cent in value of flour available for human food, the flour made by this process, containing all the nitrogenous or nutritious matter existing in the

berry hitherto lost, yields a large increase in the number of loaves per sack. From the trials which we have ourselves made, we are satisfied that that increase may be safely stated at 20 lbs. of bread per sack of flour. This, taking the common average yield of a sack of flour at 90 four-pound loaves, or 360 lbs. of bread, amounts to an increase of upwards of 5 per cent. on the bread (18 lbs. would be exactly 5 per cent.)

"The aggregate gain in flour and bread may, therefore, safely be stated at 10 per cent.

"There is also another source of gain in a national point of view, in the increased nutritive value of the the whole mass of the flour made by this process"

Dr. Dauglish, whose paper descriptive of his process of making aërated bread was read before the Society of Arts, in reference to the unbranning, states as follows:—

"The invention was brought under the notice of the Erench Emperor, who caused some experiments to be made in one of the French bakeries, to test its value. The experiments were perfectly satisfactory, so far as the making of the extra quantity of fine flour was concerned; but when this flour was subjected to the ordinary process of fermentation, and made into bread, much to the astonishment of the parties conducting the experiments, and of the inventor himself, the bread was brown instead of white. The consequence, of course, has been, that the invention has never been brought into practical operation. But, about four years ago, a French chemist, M. Mége Mouriès directed his attention to the subject of utilising for the purpose of white bread, making the nutritious substances ordinarily thrown away with the bran, and the results of his enquiries were communicated in a memoir to the Academy of Sciences, on June 9, 1856, and have since been reported on by MM. Dumas, Pelouze, Payen, Peligot, and Chevreul.

"These results explain most satisfactorily the cause of failure of the flour prepared by the American method to make white bread.

"Before the publication of M. Mouriès' researches, the nutritious substance attached to the bran was considered by chemists to be a portion of the gluten of the grain, but it now proves not to be gluten at all, but chiefly a new nitrogenous body analogous to gluten, which the discoverer has named 'cerealine,' with a portion of another well-known nitrogenous body—'vegetable caseine.'

"Among the properties of this body, cerealine, M. Mouriès gives the following:—

"It is soluble in water, and insoluble in alcohol. It acts as a ferment on starch, dextrine, glucose, or grape sugar. It alters gluten extremely, and gives to the altered matter a brown colour. Its peculiar action, when brought into contract, in the process of fermentation, with the ordinary constituents of fine white flour, is the true cause of the dark-brown colour imparted to the bread made from flour in which the cerealine was retained.

"M. Mouriès, having satisfied himself as to the properties of cerealine, adopted a method by which its peculiar action was neutralized, and then made bread by the ordinary process of fermentation, in which the whole of the bran contained in the internal coat of the grain was allowed to remain. The result was a loaf having merely an orange colour, but none of that dark-brown colour which always results when the bran contained in the internal coat of the grain is used in bread made by the ordinary method.

"In like manner, by my process, in which the fermentative changes are never allowed to take place, bread made from wheaten meal, from which only the coarse bran has been separated, is so free from the dark-brown colour that it is difficult to persuade people that it is made from wheaten meal at all."—*Chemical News.*

THE total production of pig-iron in the United Kingdom, last year, is estimated at 3,712,390 tons, the county of Durham supplying 312,030 tons.

STONE IMPLEMENTS.

AT the fourth meeting of the present session of the Liverpool Literary and Philosophical Society, on the 15th ult., Dr. HUME read a paper on "The Manufacture and Use of Stone Implements."

The author commenced by noticing the arrangement of antiquities made by Mr. Thompson, of Copenhagen, into those of the bone, stone, bronze, and iron periods; by which degrees of civilization might be studied geographically over the world, as well as historically in the modern seats of civilized nations. His objects for exhibition and illustration comprised a triturating stone, with roller and rubber,—the former from Ireland, the latter from Fermando Po; querns; numerous examples of the stone malleus; hand war clubs from New Zealand; celts, wedges, &c., from Denmark, Ireland, Fiji, England, and New Zealand; flints from the drift on the banks of the Somme; flint arrows, combs, fish-hooks, &c., from Danby Moor, Yorkshire; and numerous flint flakes, sling-stones, &c., in general from the east coast of Yorkshire. Some of the objects had been sent for the occasion by Mr. Mayer; the Royal Institution; Mr. H. Duckworth, and Mr. H. Ecroyd Smith. The triturating stone still used in New Mexico, and occasionally by the Caffres at the Cape is a first approach to grinding. It is not very different from the two stones between which the Australian natives pounded the seeds in the expedition of Burke and Wills. In the countries which have progressed, this was succeeded by the pestle and mortar, and then by the quern, the wind-mill, the water-mill, &c. The quern was usually turned by two persons, as it is still in the Scottish Highlands, and the labour was regarded as very servile, hence slaves and captives were frequently employed in performing the task. Though modern millers have laboured to destroy the stones, they are still found; in the eastern side of Asia, and the west of Europe, and in the countries of primitive habits, they are still in actual use. Numerous quotations were given from our old English literature illustrative of their use in former times. The malleus, or hammer, was of various forms, often like the sledge-hammer of a smith, a wooden handle passing through its centre. In the eleventh century, the Anglo-Saxons used "bipennis" and "stan-ex" as convertible terms, so that they seemed to have used such stone mallet, or to have thought that the Roman bipennis was of that shape. Many of those are found in connection with the bones of large animals now quite extinct. Several elegant hand war clubs were exhibited, from New Zealand,—one of elegantly carved wood, and the other of stone. Those of black stone are identical, in form and size, with specimens found in England and Ireland; but a rare and curious one was shown of the favourite material, green stone. A piece of this had been hidden during the disturbances at Massacre Bay, and so valuable was it supposed to be that a space of ground four or five acres in extent was dug over to a depth of 4 ft. for the purpose of finding it. Ancient green stone axes have also been found in our own country, as well as in France. An object of this kind is sometimes called a "sacrificing axe," and the making of it occupies a man, at intervals, about two years. He rubs it with a small flint stone, of the size of a walnut or a small egg. The chisels, or wedges, are still more varied in their forms, their uses, and the places in which they are found. Several of them were shown mounted, for the purpose of war or the chase; some were shown blocked out, others partially ground, and some with defects taken out of them by grinding. In a few instances objects in metal had been imitated in form by subsequent ones in stone. No objects were shown mounted in stags' horn; but it was shown that these are of frequent occurrence in the crannogues of Ireland, the lacustrine habitations of Switzerland, and in some of the cuttings in France. In drawing attention to the flint arrow-heads and chippings, Dr. Hume noticed the valuable researches of M. de Seithes, of Abbeville, who had added a new and important chapter to science. He had shown that instead of archæology "piecing on" to geology, the two interlace or overlap; the human or archæological period having preceded severally the changes of a geological kind.

Proceedings of Societies.

INSTITUTION OF CIVIL ENGINEERS,

November 18, 1862.

JOHN FOWLER, Esq., Vice-President in the Chair.

THE whole of the evening was occupied by the discussion upon Mr. Crawford's paper on "The Railway System of Germany."

It was observed that the paper contained an interesting description of various railway structures, rather than treated of the German system of railways. The German system of construction was, in general, no more than adopting, in a greater or less degree, the plans which had been found successful in this country, with such modifications as the circumstances required; but their works would not as a rule bear comparison with those in England. For instance, the viaducts built from the designs of Mr. J. Miller, M. Inst. C.E., upon the Glasgow and Dumfries Railway, were still unequalled in Europe for boldness of conception and excellence of workmanship, and in Lancashire there were viaducts 100 ft. in height, and in other places 150 ft. in height, and in all these cases, instead of consisting of tier upon tier of arches, as was the practice on the Continent, there was only one tier of arches. With regard to the Dirschau and the Marienberg bridges, their mathematical construction had been admitted to be faulty, there being a want of due proportion between the several parts, and their cost had certainly not been less than £45 per ton.

One of the most remarkable examples of engineering on the Continent had not been noticed. This was the line from Cologne to the Prussian frontier, between Verviers and Liège. It was constructed at an early period in the history of railways, abounded in rapid curves, and comprised an extraordinary series of tunnels and viaducts.

When Mr. Vignoles, thirty years ago, laid out the railway from Brunswick to the foot of the Hartz Mountains, he introduced what was termed in this country the "contractor's rail," but what was better known in America and all over the Continent as the "Vignoles' rail." At the same time he strongly advocated the plan of fishing the joints, first adopted in Germany.

The great principles which characterized the German system of railways were, the simplification of the permanent way, and the perfection of their statistics. All the companies were compelled, as in France, to give positive returns, under specific heads, of every detail of expenditure, and as these were published annually, the companies were brought into a wholesome competition, for the reduction of the working expenses to a minimum. A recent inquiry showed, that the expenses per train mile on two-thirds of all the German railways were within a fraction of each other. Although it would be advantageous to follow the same plan in this country, as by tracing every item of expenditure to its source, it would readily be seen where economy could be effected, yet it was believed that the average expenses per train mile were less in Great Britain than in Germany, or indeed on the Continent generally. Late returns showed that on the Semmering Railway the working expenses exceeded the receipts—so that however advantageous that railway was to the Austrian Government, it was unprofitable as a speculation. The absence of preliminary and parliamentary expenses, and the possibility of obtaining land at its mere agricultural or town value, instead of paying an exorbitant price for it, led to economy in first cost. But on the other hand, in no part of the world could work be done so cheaply as in England, whether measurement or weight of material were taken as the standard of comparison.

It was believed that, owing to the small cost, comparatively, per mile, due to the causes which had been mentioned, and to the absence of competition, arising possibly from the fact, that Government had contributed aid, either directly or indirectly, to two-thirds of the entire system, German railways were destined to pay a remunerative interest to their shareholders. Until quite lately, Parliamentary Committees in this country appeared to consider that unlimited competition was beneficial; but experience had now proved that it was not desirable for the public, and certainly not for the shareholders. It was admitted that statistical returns were invaluable to railway companies, as enabling the directors and officers to trace

the cost of each individual part of their system, it might be through a series of years, and thus at once detect any excess of expenditure. But the utility of the publication of such returns was very questionable, as it was impossible fairly to contrast the details of the cost of one system with those of another, without being fully acquainted with all the circumstances affecting the cost in each case. For instance, on some portions of the North Eastern Railway, the expenditure per mile amounted to nearly 80 per cent. of the receipts, whereas on others it did not exceed a minimum of 40 per cent. Within any particular system, where all the facts were known, such comparisons could be properly made, but as between two different companies, where the conditions were dissimilar, they would be worse than useless, as being calculated to mislead those who placed reliance on them. It was mentioned, that comparative statements, prepared with great ability from exactly the same data, of the working expenses of the two companies resulted in deductions being drawn exactly the reverse of the facts. The rules of "The Association of Government Railway Directions," as to gradients and curves, were commented upon, as practically amounting to nothing; and the condemnation of the use of cast iron for bridges seemed to be without sufficient reason, as there were many admirable examples of the use of that material for railway bridges.

It was remarked, that some years ago a curve of seven chains radius had been laid down on a line in this country, and the trains were calculated to and did run round it at the rate of 25 miles an hour; and if circumstances required it, there was no reason why curves of 300 ft. radius should not be adopted. With regard to gradients, particular districts seemed fitted for certain inclinations: thus, for instance, in the West of England 1 in 70 or 1 in 80, and in other places 1 in 100, only could be obtained, except at a greatly increased outlay. The speed on German railways appeared to be lower than was necessary. On the Semmering Railway the express trains were limited to 14 miles an hour, both in ascending and descending gradients of 1 in 40. It was asserted that this speed might be doubled with safety, and that the cost of working up the Lickey incline at 28 miles an hour was not greater than at 15 miles an hour. From 1840 to 1845, the speed on that incline was 15 miles an hour, with passenger trains of seven or eight carriages, ; whilst from 1845 to 1855, owing to an increase of traffic, the trains were composed of from ten to twelve carriages, and they were conveyed up the incline, at from 28 to 30 miles an hour, at no greater practical cost.

It was observed that, so far back as the year 1848, the German governments had taken to the belief, that a special education for engineers of all classes —mechanical and civil—was one of the first duties of a government. At that time there were regular colleges for the training of skilled workmen and for the education of civil engineers, in most of the great cities of Germany. By these means a set of thoroughly educated young men was prepared, ready to acquire practical knowledge, and to turn it to account in a very short period of time. One result of this system had been, that whereas English locomotive engines were at first copied implicitly, the German engineers gradually took to making the designs for themselves, and to depart more and more from the established patterns, so that now, on most of the principal lines, the engines were made exclusively in Germany, in some cases at a less cost than in this country, and it was said that a Berlin firm had recently tendered successfully for locomotive engines required in England.

In regard to management and economy of working, it was maintained that the public convenience was less consulted on German rialways than on English lines; there were fewer trains, the speed was very much slower, and the stations further apart. The rate of fares in Germany had not been stated, but it was believed that for the transport of goods and minerals the charges were higher. These were elements why larger dividends were realized, on comparatively smaller capitals.

To this it was replied that in Westphalia, the centre of German industry, as many trains ran as on some English lines, and the speed of the express trains was 40 miles an hour.

With respect to the construction of German railways, it was believed that the earliest lines in Germany were offshoots from the Schools of Mines in that country; and though they had no doubt taken the first ideas of railways from their great projector, George Stephenson, yet they had been carried out by themselves; and that the earliest example of an iron lattice bridge was that across the Elbe at Magdeburgh, the wooden lattice having been previously adopted in America.

The growing prominence of Germany in the industrial arts was attributed mainly to the system of technical education, particularly of engineers, which prevailed there; and it was argued that the distance between the English and German engineers was an increasing one in favour of the latter, as was deemed to be evidenced by the superior character of the continental machinery in the International Exhibition.

One of the reasons why German railways had been executed so cheaply was attributed to the population supplying an excellent industrious class, and to the works not being pushed forward so hurriedly, by which the price of labour was artificially raised. Throughout Prussia the cost of the earthworks did not exceed from eightpence to ninepence per cubic yard—the German navvy receiving only one shilling and sixpence per day. Very little plant was employed, the barrow runs were longer, and the embankments were chiefly executed in that way, instead of by tipping from waggons from a great height, which might account for their assumed superiority.

In conclusion it was submitted, that without venturing to depreciate that which was a valuable adjunct to practical men of all classes, yet undue importance must not be attached to mere technical education, in contradistinction to that practical knowledge which it was essential the engineer should bring to bear in the exercise of his profession. The history of engineering showed that the works which reflected the highest honour on this country had been carried out by men who had not received a special education, but who, being possessed of great natural genius, were enabled to take advantage of the national resourses and peculiarities in such a way as to bring the profession to the high pitch it had already attained, and to command for English engineers universal respect.

November 25, 1862.

JOHN R. M'CLEAN, Esq., Vice-President, in the Chair.

THE first paper read was on "The Hownes Gill Viaduct, on the Stockton and Darlington Railway," by Mr. W. Cudworth, M. Inst. C.E.

This viaduct was situated near to the Consett Ironworks of the Derwent Iron Company, in the north-western part of the county of Durham, on what was formerly the Stanhope and Tyne Railway, an undertaking which came into the hands of the Stockton and Darlington Railway Company, in the year 1844. Hownes Gill was a dry ravine 800 ft. in width and 160 ft. in depth, and originally the line was laid out with gradients corresponding with the natural *contour* of the ground, that on the west side being 1 in 2½, and that on the east side 1 in 3. The traffic was conveyed over these gradients for some years with little difficulty, but a large accession of trade, due mainly to the discovery of the Cleveland ironstone, rendered greater facilities of transit imperative. It then became apparent, that the erection of a high level viaduct was indispensable; and as early as the year 1844, the directors of the Stockton and Darlington Railway Company took steps with the view of ascertaining the probable cost of such a structure. It was not, however, until December, 1856, that a contract was entered into with Mr. John Anderson, to erect a viaduct of firebrick set in hydraulic mortar, and the arches in cement, in eighteen months, and to uphold it for twelve months after completion, for the sum of £14,614. The design was prepared by Mr. T. Bouch (M. Inst. C.E), and was subsequently approved, with some modifications, by the late Mr. R. Stephenson and Mr. G. P. Bidder.

The extreme length of the viaduct was 730 ft., and its greatest height from the bottom of the inverts to the level of the rails 162 ft. It had twelve semicircular brick arches, each 50 ft. span, 14 in length, and 2 ft. 6 in. in thickness. The inverted arches in the foundations, four in number, which were introduced at the suggestion of Mr. Stephenson, so as to extend the bases of the three central piers until the weight scarcely exceeded 1 ton per superficial foot, had a versed sine of 14 ft., were 38 ft. in length, and 3 ft. in thickness. The extreme height of the five loftiest piers, measured from the springing of the inverts to the springing of the arches, ranged from 114 to 110 ft.: that of the six remaining piers diminished rapidly towards each end. Their length was 14 ft. at the top, and 38 ft. at the bottom, the latter dimension corresponding with that of the inverts. The piers, to within 15 ft. of the inverts, were stayed by buttresses transversely to the line of the viaduct. At this point they were only 17 ft. 6 in. in length, but below this level the buttresses merged into the piers, when they together had a rectangular section 38 ft. in length. The buttresses were 3 ft. thick at the top, and 5 ft. thick at the bottom; their projection from the piers being increased by offsets at intervals of 35 feet. The piers, although light in their proportions, were reduced by recesses, 7 ft. 3 in. wide, and averaging 3 ft. 9 in. deep, sunk in each side, so that the horizontal section of each pier with the buttresses was in the form of a double cross, the brickwork in the middle being only 2 ft. thick. These recesses were not continuous, but were divided into three compartments in height, and by their adoption the amount of brickwork in each pier was reduced about 14½ per cent. Between the spandril walls, two internal parallel walls of stone were introduced to sustain a platform of flagging, on which the way beams and the ballast were carried. The way beams, which were of Memel timber, were at first secured to the internal walls by bolts; but as this plan was found to be objectionable, the nuts from the holding down bolts were removed, and a thickness of 6 inches of coke ballast was interposed between the way beams and the flagging. The parapet consisted of a substantial cast iron railing. The firebricks, which were of excellent quality, weighed 9 lbs. 11 ozs. each, and cost the contractor at the viaduct £1 11s. 2d. per thousand. The number used was 2,655,000. It was a gratifying fact that the work was completed without accident, and that not a single crack was to be found in the whole of the structure. The erection of the scaffolding, which was of a very light character, was considerably facilitated by the hoisting tackle being made to traverse a stout wire rope stretched across the Gill, and firmly fixed at each side. When the arches were about to be turned, the piers were stayed by two parallel wire ropes stretched from end to end of the viaduct. The first brick was laid in February, 1857, and the first train passed over the viaduct in July, 1858. The cost of the structure amounted to £15,756, the contract sum having been increased by the additional depth of the foundations, by the adoption of a heavier parapet, and by other contingencies. Regarding the viaduct as an unpierced solid, its contents would amount to 61,910 cubic yards, and its cost would be 5s. 1d. per cubic yard.

The question of the relative cost of brick and iron viaducts was then alluded to, reference being made to two works of the latter description erected by Mr. Bouch on the South Durham and Lancashire Railway. These viaducts consisted of three lines of trellis girders resting upon skeleton piers, formed of six cast iron columns, jointed at intervals of 15 ft., and braced together by horizontal cast iron struts, and by vertical and horizontal tie bars of wrought iron. The clear spans between the piers were in all cases 48 ft. The Beelah viaduct was 1,000 ft. in length and 197 ft. in extreme height. The Deepdale viaduct more nearly resembled the Hownes Gill in its proportions, being 740 in length and 160 feet in extreme height. A comparison was therefore instituted between the probable cost of such an iron viaduct erected across the Hownes Gill Valley, and one of brickwork, supposing both to be built to carry a double line of railway, and that the spread of the foundations was in each case adjusted to sustain a weight of 2¼ tons per superficial foot, including the greatest moving load. The prices of the brickwork and of the masonry were taken from Mr. Anderson's schedule; those of the timber and ironwork were the prices actually paid to Messrs. Gilkes, Wilson, and Co., the contractors for the South Durham and Lancashire viaducts, minus a deduction of ten shillings per ton for the cost of cartage over country roads. With this adjustment it was found, that the cost of the viaducts, calculated in this way, would be £20,681 for the brick structure, and £16,259 for that of iron. It was thought probable, that the interest on the difference between these two amounts, say £222 per annum, would be absorbed in the periodical examination and painting of the iron, and the depreciation of the perishable timber platform; and that at the place referred to, a brick viaduct would be, ultimately at least, as cheap as one of iron. If the viaducts were designed to carry a single line of railway, the comparison would, it was believed, be still more in favour of brick. Although the author preferred brick to stone, he by no means regarded iron as ineligible under all circumstances. In situations which did not yield suitable building materials, and where there were no cheap means of conveyance from a distance, the small relative mass of an iron viaduct would be a strong argument in its favour;

for the whole weight of such a structure, including masonry foundations, would be less than one-fifth that of brick. This circumstance would also conduce to the selection of iron in cases of doubtful foundations.

The second paper was "On the Use of the Timber of the Palmyra Palm, in the Construction of Bridges," by Mr. Henry Byrne, M. Inst. C.E,

It was stated that, in the tract of country at the northern extremity of Ceylon, known as the Jaffna Peninsula, a district embracing an area of about 400 square miles, of which the author had charge till recently, as resident or assistant civil engineer, the only timber fit for building purposes was that of the Palmyra palm. This palm grew perfectly straight to a height of 60 ft., and was of nearly uniform thickness, 10 in., from a few feet above the ground. The lower half only, however, contained sufficient woody fibre to render it useful, and in good specimens this portion of the tree, at a height of 30 ft., was from 3 to 4 inches thick, or one-third the diameter of the stem, while at the base there was little or no pith. The specific gravity of the best portion of the stem was, on an average, 1·055, and its power of resistance to a transverse strain as compared with teak as 9 to 8. A well-grown tree would yield a pile 30 feet in length, requiring only to be stripped of its outer integument (sometimes, but erroneously, called the bark) and pointed to fit it for use. The author had never had occasion to use rings to prevent it from splitting in the process of driving, while the nature of the ground was such as to render shoes unnecessary. For roadway bearers, the most efficient plan was to split the tree in half, and after removing the pith, to join the two pieces together by wooden keys. at intervals of 4 ft., and to set the beams on edge, when they would be 8 in. deep, and 6 or 7 in. thick. Five lines of such bearers, under a roadway 15 ft. wide, and supported at intervals of 10 ft., were sufficient for the heaviest turnpike road traffic, including the largest elephant waggons. In every case the roadway bearers were supported directly by piling, the plan of strutting them from the piles, or of supporting them by iron tension rods, in order to allow of wider bays, being objectionable. The first method would involve either the weakening of the piles, by notching them to receive the struts, or the use of iron bolts and straps which corroded very rapidly in that climate, and injured the timber in contact with them. By the second plan the safety of the structure would depend solely upon the iron, and would be a source of constant anxiety from the perishable nature of that material. Iron had only been used for spiking the planking to the roadway bearers, when it was protected from damp, by the concrete usually laid over the planking. As to the durability of such bridges, the first the author constructed had stood for sixteen years, without requiring any material repairs. He believed that in the most unfavourable situations the average duration of a Palmyra timber bridge might be reckoned at twenty-five years; and even then a large proportion of the material might be used in the reconstruction of it. This timber seemed to be a proof against the attacks of the teredo, and inferior specimens remained perfectly sound below the water-line, while above it a coating of tar was all that was needed to prevent splitting from exposure to the sun. Details were then given of the actual cost of twenty lineal feet of a bridge constructed wholly with Palmyra timber, 300 ft. in length, and 15 ft. wide, from which it appeared that the cost per lineal foot amounted to 16s. 6d., and it was stated that some bridges had cost from 16 to 20 per cent. less. In the district referred to, an aggregate length of about 2,000 ft. of such bridges had been built, within the last few years, across the numerous tidal inlets which intersected it in various directions.

Effects of Iron Plating.—A communication from Toulon, in the *Messager du Midi*, says:—"The laying up of the frigate, "La Gloire," in the Castigneau dock has disclosed three unexpected phenomena; first, that the contact of the copper lining and the submerged iron plates had established a galvanic current, which produced the effect of a voltaic pile, and was completely deteriorating the armour of the frigate in the parts below the water line; secondly, that a species of shell fish, hitherto unknown, was afterwards discovered among the millions of mollusce by which the hull was covered, apparently produced under the influence of the same galvanic current; and, lastly, in the hold of the vessel 22,000 litres of wine were found to be transformed into vinegar, it is not known by what influence."

TO CORRESPONDENTS.

Received.—W.S.U., P.J.W., W.N.N., G.H.B., J.H.T., G.H.B., Mr. Iron, G.W., E.K. & F.T., J.F.C., W.M. J.H.S., W.J.

A correspondent wishes for the address of X.Y.Z., whose letter on "propulsion of vessels" appeared in Oct. 31st last.

ARMOUR PLATES AND WOOD BACKING.

TO THE EDITOR OF THE "MECHANICS' MAGAZINE."

Sir,—The necessity of being brief in one's communications often puts a correspondent in the position of not writing so intelligibly as he might, and of trusting to his opponent in a discussion, to interpret fully and correctly an argument against himself, which it is vain to imagine controversialists will do. It would be expecting more, therefore, from "Civilian" than I ought, if I were surprised that he has misapprehended one of my points in favour of wood backing to armour plates; but it will be proper that I should state it now explicitly. I allude to the clear gain of a large portion of the resistance against shot which wood backing affords, because of its not throwing, I asserted, any burden in respect thereof upon the buoyancy of the vessel. I referred to the 4 and 5 ft. in depth, of the backing that is under water. Indian teak is rather a light wood, though strong for resistance; its specific gravity, when dry, is under 0.7, and, when wet, may probably be 0·75 or 0·8; consequently its displacement of water, when wholly immerged, will support its own weight and a fourth or a fifth more; so that, taking also into account the port-holes, more than a third of the wood defence must be water-borne, and the same proportion of the resistance will be freely acquired. Not so with the iron defence, which exists, as a cruel burden, upon the buoyancy of the ship.

All this is so undeniable, that no observations purporting to be a reply to it, would have been made, except on the hypothesis of misapprehension, occasioned by my brevity; and so the remarks upon it by "Civilian" are very true, only they do not touch the subject. "I must surely know," he says, "that weight for weight, and strength for strength, much greater displacement can be, and is, attained in naval architecture with iron plates than with timber." Equal weights will give equal displacements; greater tonnage, or greater displacement, consequent on greater tonnage and unequal weights, is what he means. But the question is not about the weight of the hull of a ship in relation to its strength and capacity; but about its weight in relation to penetrative resistance to shot. Nor is the question about buoyancy in relation to tonnage; but about buoyancy in relation to floating existence under fire, and, indeed, out of it too. Thus, if the iron defence is carried beyond a certain extent, the vessel sinks; but we may go on increasing the thickness of the wooden sides until they meet, and still a balance of buoyancy will remain. We get the unsinkable ship. Even so the matter stands when the breadth of beam is a given dimension, or, as though we were obliged to put both wood and iron defences within the skin of the ship; but that is not the case of the "Warrior," nor was it the case under discussion. When the defences are placed outside, it is obvious at a glance, that for all which is under water, wood is a relief, and iron is a burden to a ship.

I am sorry that "Civilian" and myself are still at issue on the question, whether wood backing presents a difficulty or a facility for the penetration of iron plates by shot and punches. It is, however, in the affirmative that I reciprocate his remark about his having "no hope of converting" me; for I *do* hope to convince him that he has made a mistake here, because his writings display that he is a gentleman of excellent good sense, who happened hastily to form an opinion of the evil of the elasticity of wood backing from the results of experiments, of which the apparent bearings only he adopted, and without giving them adequate reasoning consideration. But I wish to say that the evil to which I allude is the special one of facilitating, as it is alleged, the piercing of the armour plates, for I quite agree with him that the elasticity of the wood is truly an obstacle in the way of securely fixing them, and if it cannot be done, it will be as he says, "far better to have them riddled with shot holes which might be plugged, than 40 or 50 ft. of surface left totally unprotected" by any one of them being displaced. This could be done with heavy shot from great distances, because smashing and not perforation would be their work; and then shells of the ordinary kind could be poured in from the same distances with the ordinary guns. This is the great danger the "Warrior" will run, and may induce her to fight end on till within a certain distance, for the traditions about a raking fire are over; they have had their day, and she is well prepared by her construction for tactics of this kind.

"Civilian" speaks of me as "a theorizing critic," and directs my attention to an experiment in which one plate was backed with blocks of oak, and the other with a block of cast iron. But experiments require criticising as well as principles; they can bear a right and a wrong interpretation; and "Civilian" has certainly been unfortunate in his theoretical deduction from the one referred to. The greater effect of shot upon the wooden-backed plate, which of course was to be expected, did *not* "settle the question of rigid *versus* elastic backing," but of their iron *versus* indefinitely thick iron, for their was a conjoint resistance in the cast iron block and the plate. Wood can afford no assistance to the iron, only an independent resistance of its own; and if it could, still the question of rigidity and elasticity would not be touched, for that must be settled with rigid and elastic bearings merely, without continuous surfaces. The latter however, may be allowed in the case of wood, without any essential change in the conditions of the problem.

"Civilian" has been so good as to say, that it must have been an inadvertency on my part to contend that a wood-backing is an obstruction to the plates being perforated; on the contrary, this opinion is founded on a long experience in mechanical pursuits. He himself describes exceedingly well the *modus operandi* of the obstruction. "The yielding of the backing causes the plate to be driven inwards bodily, over an area of some feet around the point struck, and to buckle outwards at its extremities." Exactly so; and thus the work done by the projectile force is in part distributed and dispersed by implicating a larger area in the resistance, instead of being concentrated on only the surfaces in collision, as would be the case much more nearly if the plates were held up very stiffly to the blow, either by an iron framing with open panels, or by their fixture, if small, by their edges. To procure rigidity by the addition of another plate as backing, is to do more than that, and the experiment is deceptive. It is to change the conditions of the problem, because we are reasoning about a *given* thickness, or else we are not reasoning at all. This is what I meant by insisting on the necessity of conditions, in order to put "the question logically and usefully at issue"—the conditions of a special problem, and not of the wider question —iron *versus* wood—to which "Civilian" makes them refer. There are conditions absolute, on which alone, apart from any mathematical difficulties, hangs the logical possibility of the solution of a problem, and without which there is no advance beyond truisms; and there are conditions arbitrary, referring to mathematical and other difficulties, on which the proportion of abstract to concrete truth will turn. It was a condition of the former kind I dwelt upon, and the violation of which I illustrated in "Civilian's" interpretation of the experiment, in not recognising a variation virtually in the thickness of the plates. The absolute condition of a given quantity was abandoned, and no notice taken.

Yours, &c.,
Ben Cheverton.

[Though the question of "wood-backing" is an important one, we think that it has been sufficiently "ventilated" in our columns for the time. We will, however, give "Civilian" an opportunity, if he likes, to answer Mr. Cheverton's last two letters, and there the controversy must end for the present. —Ed. *M. M.*]

IRON MASTS.

Sir,—Having seen in your last week's number of the Mechanics' Magazine, Capt. Cooper Cole's plan of Iron Hollow *Sheer Masts*, I am happy to have it in my power to state, that it is by far the strongest principle of masting vessels — much superior to masts having only rigging and stays for their support. I have rigged no less than seven boats on that principle, and, consequently, I have had sufficient proof of their superior strength, which I esteem one-third stronger. This is easily imagined in considering that the *lee* standing rigging of a ship is not only no support to the mast, but from its weight, together with the wind acting upon it, tends to drag the mast over.

A mast between the sheers might well be dispensed with, and its material given to strengthen the sheers.

It was formerly thought that sheer masts, joined at their apex, could not be made sufficiently strong, but as relates to *wooden sheer masts*, I fully proved the contrary, and no doubt iron hollow sheer masts would be made much stronger.

I am, &c.,
MOLYNEUX SHULDHAM,
Dec. 3rd, 1862. Commander R.N.

Gossip.

A prospectus has been issued of the United Kingdom Railway Rolling Stock Company, with a capital of £100,000, in shares of £10 The undertaking is for the purpose of purchasing railway rolling stock, and leasing it to railway companies and others for short periods under agreements which will provide for the purchase of the stock by the companies at the expiration of a lease, the rent and purchase money being payable by quarterly instalments extending over five or seven years.

According to the general acts of Parliament 3rd Geo. 4, c. 126, s. 32, "ploughs, harrows, and implements of husbandry" and horses, cattle, carriages, &c., when employed in carrying or conveying them, are exempt from tolls: 14 and 15 Vic., c. 38, s. 4, exempts steam-thrashing machines and 16 and 17 Vic.,c.135, s.6, exempts steam-engines when attached to thrashing machines, &c. A toll collector receiving tolls on these implements can, therefore, be summoned before a magistrate of the district, and compelled to refund the money.

A prospectus has been issued of the Oxygen Gas Company, with a capital of £100,000, in shares of £20. The company propose to purchase Mr. Webster's patent for the manufacture of oxygen gas (the consideration for which is to be £25,000 entirely in paid-up shares), and to grant licenses for its use. Hitherto the cost of producing oxygen gas has been £6 per 1,000 cubic feet, and the statement is that under the present process it can be produced in any quantity at from 5s. to 10s. per 1,000 feet. The chief use anticipated for it is to produce perfect combustion in lamps, stoves, smelting furnaces, &c.

One of the specifications we described three weeks, ago, No. 751, may be termed a sensation or monster specification. It consists of 36 pages, 104 (hundred and four!) drawings, and it costs £2 13s. It measures 6 in. thick. Let us hope that it contains as much mind as it undoubtedly does matter. The patentee is Mr. Thomas Dunn, of Pendleton, Manchester, the same gentleman, we believe, whose portrait is to be seen at the Kensington Museum.

GREAT TELEGRAPH FEAT.—The unparalled feat of writing by telegraph direct through a continuous line of 3,500 miles was recently achieved in the United States. Between 4 and 5 p.m., a news message was sent to San Francisco, to which, a few minutes afterwards, a return message was received, dated San Francisco, Nov. 6, 2½ p.m. The New York message of 5 p.m. was answered at 2 p.m., or three hours before it was sent, in the usual order of time. The difference in time between the two cities is three hours and fourteen minutes. This, we believe, is the longest circuit ever worked in the history of telegraphing.

ELECTRIC AND INTERNATIONAL TELEGRAPH.—A special meeting of this company was held yesterday at the offices, Telegraph-street; the Hon. R. Grimston in the chair. The Chairman said the meeting was for the purpose of enabling the directors to consolidate into stock the shares upon which all the calls had been paid, and to authorize the raising of additional capital. In 1857 the capital of the company amounted to £740,094, and the revenue receipts for that year to £122,231. Last year the capital amounted to £912,565, and the revenue receipts to £220,548, so that in a period of seven years, while the capital had increased at the rate of 23 per cent, the revenue receipts had increased at the rate of 79 per cent. Foreign Governments were putting up land wires, which would all bring business. The increase would come from the great development of traffic on the company's system; the 900 stations would act as feeders. The main lines were gradually being choked up with traffic. To meet this increase of business the company would be prepared in May next with new lines of communication to Scotland, the North, and the manufacturing districts. The directors intend to carry out these additions by the issue of 15,000 shares of £10 each. A deposit of £1 10s. on each share would entitle the owner to be registered as having paid up £3 on the £10 shares. He then moved a resolution authorizing the conversion of 7,199 shares into stock. The motion was seconded and agreed to. The sum of 100 guineas having been unanimously voted for the relief of the distressed operatives in Lancashire, a vote of thanks to the chairman closed the proceedings.

RAILWAYS AND GOVERNMENT CONTROL.—At the last monthly meeting of the Association for the Promotion of Social Science, a paper was read by Mr. P. H. Rathbone, in which he discussed the question—"How far Railways should be placed under Government control." Mr. Rathbone took a brief review of the railway system in this country, pointing to the enormous capital invested, for which no adequate return was, as regarded many of the lines, received. After showing that it was not good for the public, though they received a temporary benefit, that any undertaking should be carried on at a loss, he contended that the capital in railways might be expended to greater advantage than at present. It was rather matter of surprise that the present depreciation was not even greater than it is. The plan he suggested to remedy the defects of the present system was to have a railway department of the Government, for making new railways or the extension of old ones, and that the actual work should be paid for as in any other case. He had also gradually come round to the opinion that the French plan of leasing railways for a number of years, and that they should eventually revert to the Government, was a desirable one. A discussion followed, during which a suggestion was made that Government ought to have the supervision of railways, as a protection to the public against accidents which were constantly occurring. Thanks were voted to Mr. Rathbone for his paper.

A TELESCOPIC LADDER.—The *Hereford Times* says that a very ingenious and admirable invention, called the telescopic ladder, has just been patented by the inventor, Mr. G. H. Morgan, surveyor and builder, New Market-street, in that city. This ladder, which might be made to a great length, shuts up like a telescope, the uppermost *floor*, so to speak, shutting up in the next, and so on to the bottom; in like manner, the first floor is easily projected, and may be turned against a wall at any angle: then follows the second, third, fourth, &c. The whole series shuts up into a small compass.

DEATH AND TRADE.—The American Government advertises for 2,000 head boards for graves. They are to be of black walnut, clear of knots, four feet long, and ten inches wide. D.W. Kolbe, of Philadelphia advertises to furnish artificial limbs at 50 dollars for each limb amputator above knee joint; or 35 dollars if amputated below the knee joint.—*Scientific American.*

THE ILLUMINATING POWER OF THE GAS SUPPLIED TO THE CITY.—At a recent meeting of the City Sewers Commission in the Guildhall, Dr. Letheby presented his report on the illuminating power of the gas supplied to the city of London during the autumn quarter by the Great Central Gas, the Chartered, and Commercial Gas Companies. The gas had been tested in accordance with the instructions of the Metropolis Gas Act of 1860. It had been tested at two places, namely, at the London Hospital and at Finsbury-square, and 325 examinations had been made. The results were, that the mean illuminating power of the Great Central Gas was equal to 13·34 sperm candles of the standard quality, and that of the Chartered to 13·78 candles, and that of the Commercial to 13·02. The weekly average of the Great Central had ranged from 12·69 to 14·93, and that of the Commercial from 12·41 to 13·85. The difference on the mean illuminating power of the Great Central Gas at the two places where it has been tested, namely, at Finsbury-square and the London Hospital, which are nearly two miles apart, differed only to the extent of 0·45 of a candle, and as the largest average (13·55) was at Finsbury-square, it was manifest that the difference was accidental. These results indicate that the gas supplied in the city by the three companies has not, during any week, been below the standard quality, and that the quarterly averages have been from 8·5 to 0·15 per cent. above it. The former is the excess of the Commercial average, and the latter of the Chartered; that of the Great Central having been 13 per cent. over the standard. Last year at this time the quarterly average of the Great Central was only 12·16 sperm candles, and the mean illuminating power of that gas for the corresponding quarter of the last seven years has been 12·55 candles. The quality is therefore improving.

Patents for Inventions.

ABRIDGED SPECIFICATIONS OF PATENTS.

THE Abridged Specifications of Patents given below are classified, according to the subjects to which the respective inventions refer, in the following Table. By the system of classification adopted, the numerical and chronological order of the specifications is preserved, and combined with all the advantages of a division into classes. It should be understood that these abridgements are prepared exclusively for this Magazine from official copies supplied by the Government, and are therefore the property of the Proprietors of this Magazine. Other Papers are hereby warned not to produce them without an acknowledgement:—

STEAM ENGINES, &c., 1337, 1340.
BOILERS AND FURNACES, 1326, 1380.
ROADS AND VEHICLES, including railway plant and carriages, saddlery and harness, &c., 1341, 1351, 1356, 1359, 1360, 1365, 1372, 1389.
SHIPS AND BOATS, including their fittings, 1329, 1336, 1346, 1362, 1370, 1374, 1381, 1397, 1405.
CULTIVATION OF THE SOIL, including agricultural implements and machines, 1355, 1369, 1379, 1391.
FOOD AND BEVERAGES, including apparatus for preparing food for men and animals, 1338, 1373, 1395, 1396.
FIBROUS FABRICS, including machinery for treating fibres, pulp, paper, &c., 1345, 1348, 1368, 1375, 1376, 1392, 1403, 1406, 1408.
BUILDINGS AND BUILDING MATERIALS—*none.*
LIGHTING, HEATING, AND VENTILATING, 1332, 1334, 1336, 1382, 1399.
FURNITURE AND APPAREL, including household utensils, time-keepers, jewellery, musical instruments, &c., 1327, 1328, 1330, 1314, 1353, 1361, 1377, 1383, 1386, 1387, 1388, 1390, 1394, 1400.
METALS, including apparatus for their manufacture, 1333, 1339, 1378, 1384, 1401.
CHEMISTRY AND PHOTOGRAPHY, 1352, 1385.
ELECTRICAL APPARATUS, 1398.
WARFARE, 1335, 1357, 1393, 1402, 1410.
LETTER-PRESS PRINTING, 1349, 1354.
MISCELLANEOUS, 1342, 1343, 1347, 1350, 1358, 1363, 1364, 1367, 1371, 1404, 1407, 1409.

1326. T. PARKINSON, J. NORMAN, and R. COTTAM. *Certain improvements in the construction of furnaces for steam boilers.* Dated May 5, 1862.

This invention consists in constructing the grate bars of the furnaces of steam boilers of steel or wrought iron tubes, connected at their ends to water chambers. A constant supply of water is introduced into these tubes and chambers, by suitable pipes, and the steam generated in them is carried off into the interior of the boiler by a pipe or pipes passing from the chamber near the bridge along the flue to the back end of the boiler, or in any other convenient manner. In order to secure the ends of the tubes into the water chambers in a cheap and efficient manner, the inventors run the metal of the chambers around the ends of the tubes. *Patent abandoned.*

1327. L. G. PERREAUX. *Certain improvements in clocks or machines for keeping time.* Dated May 5, 1862.

This invention consists:—1. In the employment of the weight of falling sand as a motive power instead of the weights and springs of ordinary clocks. 2. In the mechanism or apparatus for regulating the flow of sand, so as to give the necessary movements to the hands on an ordinary dial for indicating the time. Each apparatus is formed of three distinct parts. The first two form reservoirs, one for containing, and the other for receiving, alternately, the sand; the third is the space between them, which is adapted to receive the movement of the clock. The opening for the flow of the sand from the upper reservoir should be large enough to allow it to pass through, so as to act in an uniform manner on the hands. Three ratchet wheels are employed which have no connection with each other; they are worked by means of clicks or pawls, two of which belong to the hands, and the other to the striking part, and are moved by levers. These levers are provided at one end with a trough adapted to receive the sand, and at the other end with a counter weight. When the sand falls into the trough

its continuous flow destroys the equilibruim, and in falling imparts to the rod forming the fulcrum of the lever the necessary movement for pushing forward the clicks or pawls, and turns the wheels of the hands. The trough then empties into the reservoir beneath, and the counterweight causes it to return to its original position, to continue the same movement until all the sand has run through. *Patent completed.*

1328. H. ALLMAN. *Certain improvements in the construction of apparatus commonly called locks.* Dated May 5, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1329. T. WILSON. *Improvements in covering ships of war and land batteries with armour plates, and in the construction and steering ships of war.* Dated May 5, 1862.

In manufacturing armour plates for ships of war and batteries, according to this invention, the patentee makes the said plates either of wrought-iron or steel, or of copper, or of gun-metal, or other metal or metallic alloy which is possessed of great hardness and toughness. In making the said plates of iron or steel, he forms ribs or flanges on their surfaces, the said ribs or flanges serving to attach or secure the said plates to the ship or battery, as hereinafter explained. The ribs or flanges may either be made on the plates by rolling or forging during the manufacture of the plates, or the plates may be made without ribs or flanges, and the ribs or flanges made separately may afterwards be attached to the plates by welding or brazing; or the ribs or flanges may be made on the plates by taking flat plates and bending the edges, or portions of the edges of the plate, into planes at right angles to the plane of the plate. In making armour plates of gun-metal or other hard and tough metal or alloy, he either makes the said plates plain, or he makes them with ribs. In making ribbed armour plates of gun-metal, or other metal or alloy which requires to be fashioned by the process of casting, he forms the ribs or flanges on the plates by the casting process during the manufacture of the plates. When he makes armour plates of the alloy called Muntz's metal, that is to say, of an alloy composed of 40 parts by weight of zinc, and 60 parts by weight of copper, he either casts the said plates, and employs them without having been rolled, or he takes ingots of the said alloy, and heating the ingots to redness, he rolls them between rolls, either plain or having figures suitable to form plates, having ribs or flanges thereon. The improvements in fastening or securing armour plates to ships of war and batteries consist further as follows:—He fastens or secures the plates by means of bolts or fastenings made larger in diameter at their screwed ends than at their middle, the object being to transfer vibration to the middle or plain part of the bolt, and thereby to secure the screwed ends of the bolt from injury. The invention cannot be fully described without reference to the drawings. *Patent completed.*

1330. S. BARNETT. *Improvements in helmets for divers.* Dated May 5, 1862.

This invention consists, firstly, in constructing the discharge valve of the helmet so that the spindle of the valve projects through and slightly beyond the outside cover of the valve in which the spindle can move backwards and forwards. By pressure upon the projecting part or exterior end of the spindle, the diaphragm of the valve may be pressed inwards home to its seat, preventing the escape of air. A spiral spring around the spindle, and between the diaphragm of the valve and the outside cover, reopens the valve upon the pressure being removed. Secondly, the improved helmet is so constructed that the front eye is attached to the helmet by means of a hinged joint, the metal rim of the eye fitting into a seat of vulcanised india-rubber. The improvements further consist in constructing the metal screw collar, which unites at the neck the two parts of the diving helmet, with suitable holes, or orifices to receive a pin, so that the upper or detachable part, when screwed into its proper position upon the lower part, may be locked securely therein by means of the pin, which the inventor terms a locking-pin, the said pin being attached to the helmet by means of a chain. *Patent abandoned.*

1332. C. BINKS. *Improved methods of obtaining hydrogen gas and certain gaseous compounds of hydrogen and of carbon.* Dated May 5, 1862.

This consists in applying to the carbon or carbonaceous materials, whilst kept at ordinary temperatures, steam previously so strongly heated or superheated as to be decomposed on contact with the carbon, and, as contra distinguished from the usual method resorted to, for decomposing water through the agency of carbon, and applying to it steam of ordinary temperatures. Or, in other words, he makes the steam itself, and not the carbon, as commonly practised in such operations, the vehicle of the heat requisite to effect its decomposition, or the combination of its elements with the carbon on being brought in contact with it. *Patent abandoned.*

1333. F. MARREL. *Improvements in forming wrought-iron bars for the manufacture of armour-plates and other articles of forged iron.* Dated May 5, 1862.

This invention consists in rolling iron bars, with grooved flanges or projections of a peculiar shape, for insuring a strong joint between the bars when employed for forming a pile for the manufacture of armour plates and other articles of forged iron. *Patent completed.*

1334. J. VICTOR, J. POLGLASE, and W. ROUNSEVELL. *Improvements in the manufacture of safety fuses for mining and other purposes.* Dated May 5, 1862.

Here the tubes or external portions of the fuses are constructed entirely of metal. The patentees protect the lead or soft metal tubes by covering the same externally with strips of hard metal wound spirally around the tubes. They also make safety fuses of skelps or strips of hard metal, the metal used being zinc or other metal in a simple state, or alloy of metal or combined metals, such as plumbic zinc or other coated metals. *Patent completed.*

1335. R. BURLEY. *Improved arrangements for using ordnance under water, and in part applicable otherwise.* Dated May 5, 1862.

One important feature here consists in fitting ordnance in the lower part of a war vessel, so as to deliver its charge below water in a direction most suitable for damaging an enemy's vessel in a part rendered comparatively vulnerable by the absence of armour plates. *Patent completed.*

1336. R. BIRSHBY. *Improvements in lifting or lightening ships for entering shallow harbours, or docking and other purposes.* Dated May 5, 1862.

This consists in the employment of tanks or buoys, suitably arranged and adjusted for raising ships, whereby they are caused to draw less water, and their entry into shallow harbours or docks facilitated. *Patent abandoned.*

1337. J. ROSCOE. *An improved lubricator for steam engines* Dated May 5, 1862.

This consists in so constructing a lubricator as to enable tallow to be used as the lubricant, and, further, in adjusting thereto an air pipe or vessel for the purpose of forcing out the lubricating matter (as described), thereby rendering the lubricator especially adapted for locomotive engines when going down inclines. *Patent completed.*

1338. P. L. A. T. SOURBE. *Improvements in maturing spirits and wines.* Dated May 3, 1862.

Here, while the spirit or wine is contained in a porous vessel, by preference the wooden cask in which it is originally stored in the country where it is produced, the inventor heats and cools it alternately several times successively, the cask or vessel being securely closed during the whole operation, so that the heating process produces a considerable pressure within the cask or vessel, so much so that the liquid, to some extent, sweats through the pores of the wood or material of which the porous vessel is composed, and evaporates at the surface. When the heating process is discontinued, and the spirit or wine allowed to cool, a partial vacuum is produced within the cask or vessel, and to supply this air gradually enters through the pores of the cask or vessel. *Patent abandoned.*

1339. E. B. WILSON. *An improvement in machinery or apparatus used in the manufacture of malleable iron and steel.* Dated May 5, 1862.

This relates to the vessel in which the molten metal is treated during its conversion into malleable metal or steel, and consists in providing such vessel with a central, or nearly central, exit for the gases, such exit or escape passage dipping at its lower lip into the molten metal, and extending to within a short distance from the bottom of the vessel, at or near the centre thereof. A space is left round the gas exit passage between its exterior sides and the inner sides of the vessel, with the exception of a portion on one side, which is left to form a convenient outlet for emptying the vessel. Provision is also made for hanging the vessel on centres or pivots at each side thereof. The molten metal having been run into the vessel, air is blown therein at one or more separate points of, or entirely round, the top space, which air, after passing under the lip, permeates the molten metal and escapes with the gases up the outlet. *Patent completed.*

1340. H. JOHNSON. *Improvements in steam generators.* (A communication.) Dated May 5, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1341. J. A. *Improved apparatus for measuring and indicating distances travelled by wheel carriages.* Dated May 5, 1862.

This apparatus the patentee calls an odometer, or carriage distance indicator, and is such that it may be shown in a variety of forms. In the most complete of these arrangements he shows the termination of each mile by the sudden projection of a pin, stud, or other indicator, on the face of the instrument, so that it shall be readable by the touch when it cannot be seen, the total distance also being registered on a dial. In another arrangement he shows the distance by hands on a dial only, and the apparatus is also capable of being made both in form and size to resemble a watch. The indicator may be fixed in any part of the carriage, or may be held in the hand without at all interrupting the action of the instrument. The indicating portion of these instruments he connects with the driving part of carriage wheels by an air tube, and actuates them by a stud or other projection fixed to the stock of the carriage wheel, and which, at every revolution of the same, will be brought into contact with the driving part of the apparatus, which he calls the blower. This is fastened to the axle tree of the vehicle, and will force the air through the connecting tube into the air chamber of the indicator, and so give motion to that part of the instrument. *Patent completed.*

1342. B. COOKE. *An improved construction of implement for cutting turf.* Dated May 5, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1343. T. GABOURG. *Improvements in machines for the purpose of uniting together, by means of screws, leather used in the manufacture of boots and shoes and other articles composed of two or more pieces of leather.* Dated May 6, 1862.

This consists in the construction of a machine which will form a thread upon a continuous length of brass wire, at the same time cause it to penetrate by screwing in any portion of leather, or such like material, so as to unite them in one. *Patent completed.*

1344. R. MILLS. *Improvements in washing, wringing, drying, and mangling machines.* Dated May 6, 1862.

This consists in placing in the interior of the barrel of washing machines an oscillating beater, constructed with bars, or having perforations therein, or projections thereon, so that the materials to be washed may rub against the said bars or projections, and the water pass between the said bars or through the perforations. *Patent completed.*

1345. A. MOREL. *Improvements in heckling machines.* Dated May 6, 1862.

This consists in an arrangement of annular and other parts, which enables the patentee to multiply at will the parts working on the material, which is around a circle in optional proportions, thus increasing the working and consequently the production of the machine. The details of the invention are voluminous. *Patent completed.*

1346. G. BORTHWICK. *Certain improvements in the construction of ships and boats, and certain other floating bodies.* Dated May 6, 1862.

This consists in building the deck and other superstructure of the ship, boat, &c., upon two or more pontoons or water-tight cylinders, placed parallel to each other, one pontoon constituting the support of each side of the ship, boat, &c. The pontoons are to be firmly stayed inside, and connected and bound together on the outside, and are to support the superstructure of the vessel above the surface of the water. *Patent abandoned.*

1347. P. CHENAILLIER. *Improvements in apparatus for concentrating liquids, or for condensing alcoholic or other vapours.* Dated May 6, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1348. JOHN CLARK and J. RICHMOND. *Improvements in looms for weaving.* Dated May 6, 1862.

This invention consists in weaving textile fabrics, such as plain and fancy tweeds, doeskins, merinoes, silks, satins, sarcenttes, ribbons, scarfs, broad silks, broad cloths, shawls, handkerchiefs, and the like, in the following manner:—The patentees attach to each leash cord a number or series of loops and pattern cords, by which the patterns may be varied. The invention may be used in connection with the jacquard machine, satin jacks, or any other machine now in use, to make any kind or style of pattern, merely by the attachment or detachment of the pattern, cords, and loops which are placed above the compass board in the present loom. The levers are raised in succession by means of treadles. The same set of cords will make any pattern that may be desired, instead of requiring new cords, as in the jacquard machine. *Patent completed.*

1349. W. RICHARD and J. RICHARD. *Improvements in the manufacture of printing types, spaces, and quadrats.* Dated May 6, 1862.

This relates to adaptations or combinations of parts or means for effecting the operations technically called rubbing, putting up preparatory todressing, and dressing, and comprises much detail which we cannot quote here. *Patent completed.*

1350. J. H. JOHNSON. *Improvements in the manufacture and production of minium or red lead.* (A communication.) Dated May 6, 1862.

This consists in the conversion of the oxide of lead, when free or uncombined, and of certain base salts of lead, into minium or red lead, by mixing the same with either carbonate of potash or carbonate of soda, or mixtures of the same, and subjecting such mixtures to the action of an elevated temperature, whereby the oxide of lead is oxidized, and is converted into minium or red lead. *Patent completed.*

1351. W. GREAVES. *Improvements in safety stirrup bars* Dated May 6, 1862.

Here the stirrup straps are suspended from the saddle tree by bracket pieces, or bars rivetted to the saddle tree, each bar being provided with a spring lever, over which the strap hangs. These lever bars are made with a projection or tail piece forming an obtuse angle with the end, where the lower bars are jointed to the fixed bar, the spring or springs acting upon a rounded part of the lever bar, and tending to keep the lever bars shut down upon the fixed bar, in which closed position the end of the lever bar enters a slot or recess in the fixed bar, and protects the spring from wet. The part of the fixed bar which contains the spring bar inclines upwards slightly from the pummel of the saddle, and stands out clear of the side of the saddle, so as to allow the stirrup strap to slip off freely, should the strap be thrown over or across the seat of the saddle. Should the stirrup strap be dragged back and downwards, it will be drawn along the spring lever bar until it exerts a pressure against the tail piece, whereupon the lever bar will be elevated or inclined, and will instantly allow the strap to slip off the end and over the tail piece. The flap or support of the bar is so shaped and constructed that it affords great additional strength to the saddle tree, and thereby prevents the point or bar of the tree itself from breaking away. *Patent completed.*

1352. J. H. JOHNSON. *Improvements in the manufacture of soda and potash and of their carbonates.* (A communication.) Dated May 6, 1862.

This consists in mixing natural or artificial sulphate of soda, obtained by the decomposition of marine salt, chloride of sodium, by sulphuric acid, or by sulphate of iron, with about 35 per cent. by weight of powdered charcoal, or its equivalent of coal, anthracite, or other suitable reducing organic substance, and then subjecting this mixture to a red heat, either in closed vessels or in a reverberatory furnace under the influence of a reducing flame. The mixture is maintained at an elevated temperature so long as carbonic oxide is disengaged. When this ceases to be produced, and when the sulphate is transformed into a sulphuret, the operation is discontinued. The mixture is now allowed to cool, the air being excluded. The fixed mass is then treated with hot water. The solutions or liquors are now subjected to a boiling temperature with some sulphurizing agent. *Patent completed.*

1353. W. CLARK. *An improved buckle or fastening.* (A communication.) Dated May 6, 1862.

This buckle is formed of a frame in two parts of unequal length, jointed together, having several bridge or tie pieces, over and under which the strap passes; one end of the strap is connected to a bridge piece of the smaller part of the frame, and the end passing through the several bridges of the other and larger frame. In order to hold the strap, a cross bar or rocking piece is placed about midway of the larger part of the frame of the buckle, which, when tension is exerted on the strap, is caused to bear on it its whole width, and so retain it in its desired position. To unfasten the strap, it is only necessary to raise the larger end of the buckle on its hinged joint, when the strap is free to be removed. *Patent completed.*

1354. W. CLARK. *Improvements in cylinder printing apparatus.* (A communication.) Dated May 6, 1862.

This consists in a mode of printing called "flat-plate" printing, with a speed ten to twelve times greater than the ordinary mode of roller printing, and working with greater nicety. For this purpose the patentee uses rollers, the diameters of which may be as large as is required for strength,

but which present, on a limited part only of their circumference, the engraving intended to produce the impression with this essential peculiarity, that the engraved part (whether embossed or sunk), shall be on the surface of portions of cylinders, and project from the roller concentrically to its axis. These rollers are so disposed as to produce successfully, as regards the part on which they act, and simultaneously as regards time, the impression of the proper colour. The machine is so disposed that each printing roller only acts at the time the projecting part is passing which carries the engraving, they, during the rest of their revolution, exerting no action on the pressing cylinder, but, as the latter in its motion causes the fabric to advance to a greater extent than the space occupied by the impression of the design, a peculiar contrivance is employed, which turns the pressing cylinder in a backward direction, and, consequently, the fabric with it the exact quantity required for the next impression, to unite and correspond perfectly with the foregoing. *Patent completed.*

1355. J. E. RANSOME, W. COPPING, and L. LANSDELL. *Improvements in harrows.* Dated May 6, 1862.

According to this invention, the patentees make the fastenings of the teeth independent of the fastenings of the frame. *Patent completed.*

1356. W. E. NETHERSOLE. *Improvements in parts of railway trucks and waggons, parts of which are applicable to railway carriages.* Dated May 6, 1862.

Here the inventor proposes to make the draw bar, the ends of which are enclosed in a cradle, act upon springs of india rubber, which springs are to be attached or fixed on the ends of the side chain rods. On the ends of trucks the inventor places an end door or flap, which, when opened, forms a shoot for facilitating the tipping from railway waggons. *Patent abandoned.*

1357. W. JUDSON. *The use of caoutchouc or india rubber for, and its application to guns, mortars, and other fire-arms, to resist the forces of the recoil and re-action in firing.* Dated May 7, 1862.

Provisional protection has not been granted for this invention.

1358. E. BOURDON. *Improvements in the construction of blowing fans, which improvements are also applicable to centrifugal pumps for raising water and other liquids or gases, or for exhausting the same.* Dated May 7, 1862.

The patentee claims, 1, The construction of apparatus for raising, forcing, propelling, or exhausting air, water, or other fluids or gases, in which an external hollow casing, or drum, with or without partitions and vanes formed inside, is caused to rotate, and in which the air, water, or other fluid or gas enters the said hollow drum through one or more openings, and is caused to revolve with it, such air, water, or other fluid or gas being thereby thrown into the open end of a stationary tube or tubes, or their equivalents, situated inside the said revolving drum, through which tube or tubes the air, water, or other fluid or gas is conducted out of the drum again to where required. 2, The various arrangements of blowing fans, as described. 3, The construction of exhausters, with or without hydraulic joints, for use in gas works, or other localities, as described. 4, The construction of centrifugal pumps for raising water, or other liquids, or for regulating motive power, as described. *Patent completed.*

1359. C. V. T. DE BERVILLE. *An improved safety coupling bar for locomotives and other railway carriages.* Dated May 7, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1360. P. H. COLOMB. *Improvements in arrangements and apparatus for signalling.* Dated May 7, 1862.

This is applicable for communicating signals between vessels at sea and the shore, and for other purposes. The principle of its action consists in the use, for night signals, of flashes of light, separated by intervals of darkness, such flashes being of varying duration, and a certain number of long or short flashes, or the combination of a certain number of long with a certain number of short flashes, being taken to represent a certain number, letter, or other distinguishing character of any required or pre-arranged code of signals. *Patent completed.*

1361. T. MARKLAND. *Certain improvements in wearing apparel.* Dated May 7, 1862.

This relates to a mode of ornamenting and preserving the edges of various parts of dress or wearing apparel, such as collars, facings, and the brims of hats, and consists in applying to the edges of articles of this kind a beading composed of china clay, or other suitable and similar composition, such beading being grooved or clotted longitudinally to receive the edge to be ornamented, and formed either in a curved or other shape, and of one or more pieces, to suit the article to which it is to be applied. In some instances, as when used for collars for the neck, a broad tape may be employed, which has been previously prepared for the purpose by having a cord or enlarged selvage formed upon one edge, by which the beading is effectually secured to the edge of the collar or tape, the collar or tape being slipped into the slot in the beading from the end longitudinally, and a corresponding enlargement being formed in the slot to receive the cord. The beading is produced in lengths to suit the article to which it is attached, thereby allowing the beading to yield without breaking. *Patent completed.*

1362. T. H. HOPWOOD. *Certain improvements in the means or apparatus to be employed for the purpose of raising sunken vessels, or other submerged bodies, and also in the application of a self-acting balance and regulator to the pontoons used therein.* Dated May 7, 1862.

This consists in a novel arrangement, application, and construction of pontoons, or air cylinders, for raising sunken or stranded vessels, or other submerged bodies, or for raising vessels in dock for repair; and, further, in the use and addition of a balance and regulator to such pontoons, to retain them in any position required whilst submerged. *Patent completed.*

1363. C. CLARK. *An improved cigar tube.* Dated May 7, 1862.

This consists of a hollow mouth-piece, terminating in a small tube, perforated, pointed, and barbed. In using this mouth-piece, the piercer (or pointed end) is inserted at the end of the cigar, or at the side, if necessary. *Patent abandoned.*

1364. N. WOOD and J. STOCKLEY. *Improvements in grinding, smoothing, and polishing plate glass.* Dated May 7, 1862.

This invention has reference to a previous patent, dated November 16, 1860 (No. 2,815), and comprises arrangements for causing the bench or table on which the glass rests to travel longitudinally, such motion being imparted by a rack and pinion, or worm-wheel and screw, or screws and nuts. The bench or table is set level by adjusting keys. The upper portion of the bench or table is raised or lowered by eccentric rollers, mounted on the under frame, and special contrivances are used to give the requisite lateral motion. The apparatus also consists of an upper portion, on which the glass rests, and an under frame, supported on flanged wheels, bearing on fixed rails. The polishing cylinders are made with a metal or wooden core, covered with several pieces of felt, seamed and pressed together, and formed into pieces wedge-shaped in cross section, and set radially round the core. The details of the invention are voluminous. *Patent completed.*

1365. J. J. CORDWAINER and A. CHAPMAN. *Improvements in apparatus for preventing collisions on railways.* Dated May 7, 1862.

This consists, 1, In a method of constructing retarding breaks, which can be made self-acting, and are intended to be fitted to the break van, and to all carriages, or to any required number of carriages of a train. 2, In a method of constructing a stopping break, which can be applied at any moment, and may be used apart from the retarding break, or in conjunction therewith. 3, In an arrangement of gearing for actuating the above breaks. The details of the invention are too elaborate to be quoted here. *Patent completed.*

1366. R. A. BROOMAN. *An improved box or apparatus for containing and igniting matches.* (A communication.) Dated May 7, 1862.

This box or apparatus consist of an outer cylinder and of an inner cylinder, formed with vertical compartments all round, each intended for the reception of one match or taper. The top of the inner cylinder is toothed, and a pawl takes into the teeth to prevent its being moved beyond the extent of one match compartment at a time. A stud rising through the top of the box is connected by a coiled spring to the inner cylinder. A tube containing a helical spring is fitted at the side of the outer cylinder. The spring has fitted to the top a block or table, which projects inwards, and moves up and down in a slot in the tube. There are also connected to the top of the spring two finger pieces for the purpose of depressing the spring and block. The matches are placed in the compartments with the prepared ends upwards, and the apparatus is worked thus:—Depress the helical spring, when the block will be taken below the level of the bottom of the matches, turn the inner cylinder, when one match will be brought over the block, release the spring, and the match will be forced up in the compartment, and the prepared end passing through spring jaws in the upper part of the apparatus, will become ignited by the friction in passing through them, and the lighted match will be presented and held ready for use. The internal cylinder may be fitted with holders for containing cigars, sealing-wax, or any other article. *Patent abandoned.*

1367. R. A. BROOMAN. *Improvements in swings.* (A communication.) Dated May 7, 1862.

The object of this invention is to construct a swing which can be operated by the hands or by the feet, or by the hands and feet combined, of the person or persons seated in it. The inventor attaches ropes, straps, or bands in front of and behind the ordinary point of suspension, their lower ends reaching and being attached to a moveable cross bar or sliding thimbles placed a few feet above the seat; a rope or strap, with a loop or handle, to be taken hold of and pulled by the person or persons seated in the swing, is suspended from the cross bar. He attaches a footboard beneath the seat, the front of which is connected by a rod or rope to the cross bar. The seat is suspended in the ordinary manner. On the person or persons seated in the swing pulling the rope suspended from the cross bar, or pushing the footboard with the feet, or using both hands and feet, the swing will act or be set in motion. The cross bar is, by preference, made to slide on the ordinary suspension rods or ropes. *Patent completed.*

1368. J. COMBE. *An improved machine for spreading and drawing into sliver: flax, hemp, jute, and other fibrous substances.* Dated May 7, 1862.

This consists in arranging mechanism so as to cause the fibrous substances to be fed into the machine in a direction transverse to the fibres, parallel to the axes of the drawing rollers, and so that the fibres are taken hold of by the drawing rollers sideways, by which a more equal and uniform sliver is produced than by the old machine. *Patent completed,*

1369, G. T. BOUSFIELD. *Improvements in applying steam power to tilling land by means of a digging locomotive.* (A communication.) Dated May 7, 1862,

The object here is to enable a digging locomotive to be directed with great facility, and the invention consists in securing the front pair of wheels to separate upright spindles, which can be turned simultaneously in the same direction, to cause both wheels to assume the desired obliquity to the frame of the machine. Another object is to enable a digging locomotive to be turned with facility in a short space, and consists in combining two independent driving wheels at the opposite sides of the carriage with the driving mechanism, so that, by raising the carriage upon one of the said wheels a greater distance than upon the other, one of the said wheels is put into gear with the driving mechanism, while the other is not, whereby the driven wheel can propel the carriage round in a circle nearly concentric with the opposite and independent wheel. *Patent completed.*

1370. J. HALEY. *Certain improvements applicable to ships, boats, and batteries.* Dated May 7, 1862.

This consists in applying to the exposed parts of ships, boats, and batteries, plates and bars of iron, steel, or other metal, single or combined, which plates and bars shall exhibit angular projections called cutters, formed either upon or attached to the said plates and bars in a vertical, horizontal, or diagonal directinn, or otherwise, and so tempered as to resist and destroy any projectile that may come in contact with the same. *Patent abandoned.*

1371. W. COSSAGE. *Certain improved apparatus to be used in the manufacture of soap.* Dated May 7, 1862.

The patentee claims the construction of apparatus to be used in the manufacture of soap, which provides for withdrawing the contents of the pans or vessels used in such manufacture, by causing the pans to be closed with lids or covers, and subjecting such contents to the pressure of steam or air on their surface, so as to the same to be elevated or driven through a pipe or pipes communicating with the interior of such soap pan or vessel. *Patent completed.*

1372. D. MARCHAL and A. C. DE WIART. *An improved method of preventing the destructive effects of vibrations or jar on the permanent way of railways, and on the wheels, axletrees, and other parts of carriages, and the working and other parts of machinery liable to shocks.* Dated May 7, 1862.

This consists in the application to those parts which are liable to shocks of a band, plate, washer, or lining of lead, tin, zinc, copper, or an alloy of these metals, or either of them. The same principle for neutralizing the effects of concussion, may be applied to various parts of machinery, and to the bearings of iron bridges. *Patent completed.*

1373. J. MCCANN. *Improvements in the mode of, and apparatus for, dressing, cooling, and cleaning grain.* Dated May 7, 1862.

The patentee claims, 1, The general construction and arrangement of apparatus for drying cooling, and cleaning grain, as described. 2, The system of drying and cooling grain by causing it to descend through long cases of wire gauze, perforated metal, or other suitable permeable material, whilst under the influence of currents of hot or cold air, according as the condition of the grain may require, as described. *Patent completed.*

1374. J. HAY. *Improved arrangements to facilitate the cleaning and repairing of ships' bottoms.* Dated May 8, 1862.

This consists in applying weight above the centre of gravity to one side of the ship, until that side is brought sufficiently down in the water to cause the opposite side of the bottom to be exposed as far as necessary. The arrangements for effecting this, according to one modification, consists in forming water-tight compartments or casings along the inside of the ship's bulwarks, or at as high a part of the ship's side as it is possible or convenient. Pumps, arranged to be worked by manual, steam, or other power, are provided, along with sets of pipes and valves for filling the compartments or casings with water, to depress the side of the ship, and discharge valves are likewise provided for emptying the compartments when the ship is to be righted again. *Patent abandoned.*

1375. W. P. GAULTON and M. BOOTH. *Improvements in apparatus or machinery for damping and steaming fabrics, part of which improvements are applicable for distributing fluids for other purposes.* Dated May 8, 1862.

This consists in the use, in place of the rotating brush, of a series of jets, each of which is formed like the flat flame gas burner. These jets are fixed or formed in, or communicate with, a pipe placed at right angles to the direction in which the fabric passes, and the water or fluid is supplied to the pipe from a cistern fixed at a sufficient height, and giving a constant pressure, which cistern may be filled by a pump, or other means. The inventor employs moveable boards or obstructions, so as to cut off all or any portion of the stream of water or fluid delivered by the jets, so that the quantity of water or fluid thrown upon the fabrics may be properly regulated. *Patent abandoned.*

1376. W. RIDDLE. *Improvements in hydraulic and other presses in packing machinery, and in treating cotton and other fibrous substances.* Dated May 8, 1862.

This invention relates to the doors and apparatus (where the packed bale is delivered), of a hydraulic or other form of press, for packing cotton, &c., the object of the invention being more advantageously to introduce and bend or fold the metal bands, by which the bale is to be bound or hooped. *Patent completed.*

1377. A. BEARNE. *Rendering the heels of boots, shoes, and goloshes elastic to pressure.* Dated May 8, 1862.

In constructing the heels of boots, shoes, and goloshes, the inventor hollows out the heels internally, and places within the cavity an elastic bed or cushion, or bed or cushion of vulcanite, or other suitable material of a sufficient size to present an elastic medium when pressed upon by the heel of the wearer; a thin covering of leather or other suitable material is placed over such cushion. *Patent abandoned.*

1378. W. SOUTHWOOD. *Improvements in machinery for pulverising ores and extracting metals therefrom, part of which is applicable to breaking stones.* Dated May 8, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1379. J. FOWLER and J. KING. *Improvements in apparatus for tilling land by steam power.* Dated May 8, 1862.

In tilling land by steam power, it is frequently desirable to use the ordinary agricultural steam engine, provided it can be done without altering or fitting the agricultural engine. By this invention this is very conveniently done by mounting hauling apparatus, or apparatus which gives motion to the rope for actuating the tilling implement on a carriage with disc wheels, as is now used to carry the pulley round which the rope passes when it arrives at the headland opposite to that on which the engine traverses. The disc wheels, by cutting into the land, enable the "hauling carriage" to offer sufficient resistance to a sideway strain to allow of its drawing the tilling imp'emen without itself moving in the direction of the strain. In place of disc wheels, coulters, or plates, cutting into the

land, may be used. The hauling carriage, when at work, is coupled with the engine, preferably with a flexible coupling, and the hauling apparatus is driven by the engine. On the hauling carriage is a small drum, which receives motion from the driving power, and winds up a rope laid out along the headland, thus drawing the hauling carriage forward and also the engine with which it is coupled. *Patent completed.*

1380. P. TATE. *Improvements in smelting furnaces.* (A communication.) Dated May 8, 1862.

Here the patentee builds smelting furnaces, the horizontal section of the interior of which is of an oblong, rectangular form, the interior being of that form at any point of its height. The lengthened or oblong form of the parallelogram described is such that two sides of the furnace are extended to a considerable width, and disposed comparatively near to each other, and at which sides he introduces the tuyeres, there being a series thereof distributed through the entire length of the sides. These tuyeres are so arranged as not to be directly opposite to each other, but the one to be midway between each two on the opposite side. In the ends of the furnace he disposes the apertures for drawing off the metal. *Patent completed.*

1381. C. LUNGLEY. *Improvements in apparatus for manœuvring ships and vessels.* Dated May 8, 1862.

This apparatus consists of a blade or other instrument, or of two or more such blades or instruments, caused to reciprocate or move with a to and fro or oscillating motion, by means of a steam-engine or other motive power, and to change its or their inclination at each reciprocation, in order that the full manœuvring effect may be exerted upon the vessel to turn her in any direction desired. The apparatus may be fitted either on the sides, or under the quarters, or at the bow; but the patentee prefers to place it at the stern near the propeller in screw propelled vessels. The steam-engine of the vessel may be used to work the apparatus, or an auxiliary engine may be applied. The apparatus may be used either as a simple rudder or as two or more rudders, instead of the ordinary rudder, or for forcibly manœuvring a vessel and changing her direction. *Patent completed.*

1382. G. C. GRIMES. *Improvements in the manufacture of cigar lights, splints, matches, and tapes or vestas, and in machinery or apparatus employed therein.* Dated May 8, 1862.

This invention relates, 1, To the manufacture of cigar lights, adapted particularly for striking into the ends of cigars before ignition. The patentee mixes and grinds a pastile composition, which may be such as ordinarily used in the manufacture of cigar lights, but to which he adds fine charcoal in powder, or cascarella or other powder adapted in quantity to form a sufficiently plastic composition that will admit of being rolled into a thin cake, the quantity of powder required being readily ascertained by adding it in small quantities till the desired consistency is obtained. The improvements relate, 2, To cigar lights formed on splints, and consist in saturating or coating the splint upon which the pastile composition is applied with a solution or coating of ignitable matter or composition, such as chlorate or nitrate of potash. The improvements relate, 3, To dipping the ends of splints, upon which pastile composition is to be applied, in a resinous or waxy matter, or composition that will not readily melt, at ordinary temperatures, but which, when pastile composition applied thereon is ignited, will, by the heat thereof, admit of the splint slipping out, and leaving the ignited matter in or on the cigar. Common wax answers the purpose very well, but it is made harder and more suitable by the addition of a little resin or such like substance, and he mixes a little of some agreeable scent with it to neutralize or qualify the smell from the wax or resin employed. He then dips these prepared ends of the splints in the pastile composition, and furnishes them in the usual way. The improvements relate, 4, To the manufacture of cigar lights by substituting for wood or metal splints the use of cotton or other suitable fibrous material, coated with wax, stearine, or other composition, as in the manufacture of tapers or vestas, by combining with the wax or stearine, or other coating employed to the fibre, charcoal and scent with ignitable substance, as chlorate or nitrate of potash, amorphous, phosphorous, separately or combined, so as to make a light to burn with a flame or only to smoulder. The improvements relate, 5, To means of forming wax stearine or other composition tapers or vestas. The improvements relate, 6, To means for cutting splints. The improvements relate, 7, To means or apparatus such as for which letters patent were granted to the present patentee and George Bell, on the 21st December, 1854 (No. 2691), in which bars or pins are used to act by their ends upon the ends of splints in a trough to push such pins into clamps. *Patent completed.*

1383. A. P. PRICE. *Improvements in straps or bands for securing articles, parcels, or luggage.* Dated May 8, 1862.

This invention consists in imparting a certain amount of elasticity to such straps or bands by introducing therein a length or lengths, a ring or rings, or other suitable arrangement, of vulcanized india rubber, or other similar elastic material, whereby the force necessary for the tightening and securing of the strap round any articles, parcels, or luggage, is considerably reduced, whilst the elasticity of the vulcanized india rubber, or other similar elastic material employed, tends to contract the strap firmly over the article or articles after the buckle or fastening has been secured. *Patent abandoned.*

1384. A. KINDER. *Improvements in the manufacture of sheet metal.* Dated May 8, 1862.

This invention relates to an improved and combined process for the manufacture of sheet metal or foil from blocks of lead, tin, or other soft or ductile metal, capable of being acted upon by a cutting tool or knife and rolls. According to this invention, the inventor proposes to produce sheet metal by the combined operations of cutting and rolling; and in carrying out the same, he first produces a sheet of metal by cutting it from a cylindrical block or pig, by means of a suitable knife or cutter, after the manner described in the specification of H. W. Winsburst, dated the 1st of July, 1858 (No. 1,481), and after a sheet has been so formed, or during its formation, and as fast as it proceeds from the cutting machine, he proposes to pass it between one or more pairs of rolls, which, by exerting a pressure upon the sheet, tend to condense it and render it more homogenous in its texture. The sheet is primarily cut thicker than is required for use, and it is then consolidated and reduced in thickness by the subsequent rolling process. *Patent abandoned.*

1385. L. DE LA PEYROUSE. *Improvements in treating neutral and acid fatty or oily substances, resins, and resinous substances, and compounds or products containing paraffin.* Dated May 8, 1862.

This invention consists in subjecting the above-mentioned substances, compounds, or products containing the same, to the action of azota sulphuric acid, or of sulphuric acid containing azota sulphuric acid in solution, and to the products of the decomposition of azoto sulphuric acid by means of water, and also to the products of its decomposition by means of water and of organic matters. The invention further consists in subjecting the substances before mentioned to the action of a salt, or compound of nitric acid, such as nitrate of soda, or any other suitable nitrate, in conjunction with sulphuric, or any other suitable acid, with the addition of a reducing substance or agent, such as treacle, sawdust, starch, or any other suitable reducing agent, so that when these substances react upon each other, the nitric acid may be reduced, and the desired compound of nitrogen may be produced. The improvements also consist in subjecting the substances and products firstly, before mentioned, to the action of a nitrate, such as nitrate of soda, or any other suitable nitrate, in conjunction with an acid, such as sulphuric acid. *Patent completed.*

1386. N. THOMPSON. *Improvements in barometers.* (A communication.) Dated May 8, 1862.

This invention applies to mercurial barometers, and comprises improvements by which they may be made portable. In carrying out the invention the inventor prefers to take a 36-inch glass tube, sealed at one end, and having a syphon at the other end; a metal air-tight stop-cock is connected to one end of the syphon by an india-rubber metallic tube, also air tight, and a glass bulb or fountain is likewise connected to one end of the stop-cock by a similar india-rubber air-tight tube, the other end of the glass bulb being covered with chamois leather to admit air. The glass tube is to be filled with clean, pure mercury, and the bulb two-thirds full; the tube can then be framed according to taste, and worked by a scale and vernier by means of a screw 20 turns to an inch at the upper end, or by means of a rack or pinion, and a thermometer placed in the front or at the side of the scale. He hangs the barometer plumb, then turns the thumb-screw in the back to a perpendicular; the mercury in the tube will then descend to a proper level to render the instrument portable. He inclines it gently to an angle of 45 deg., when the mercury will completely fill the tube, then turns the thumb-screw directly across the instrument, when it may be carried with safety. *Patent abandoned.*

1387. G. F. GREINER and J. H. C. SANDILANDS. *Improvements in the construction of pianofortes.* Dated May 9, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1388. MCILROY. *An improved invalid bedstead.* Dated May 9, 1862.

In carrying out this invention the hollow part is hinged at about one-third of the length from the head, for the purpose of being raised or lowered, for the comfort and convenience of the invalid, by means of the following combination of pinions and segments:—A shaft runs across the bedstead, having two cog wheels, which shaft is turned by a handle at either side of the bedstead; there are two segments, one on either side of the bedstead, which work in the two cog wheels, which segments are fastened to the frame which raises up the invalid, and also by means of the following combination of cords and pulleys:—There is a bearing from the top part of the bedstead in which is attached a pulley; a pulley is also attached to the part of the frame which is raised up, and a cord passes through the pulley enabling the invalid to raise himself to any inclination, and to remain at any required elevation. There is a ratchet wheel attached to the shaft which passes across the bedstead, and a pawl or catch fastened to the bed rail drops into the ratchet wheel and retains the bed at any elevation, and prevents it falling back. *Patent abandoned.*

1389. L. D. AUBREVILLE. *A new kind of metallic cross sleepers for the construction of railways.* (A communication.) Dated May 9, 1862.

These improved railway metallic cross sleepers are composed of two plates or sheet iron pieces about 10 in. wide, 50 to 54 in. long, and from 2 to ⅜ths of an inch thick. The edges of the said plates are bent at right angles so as to form flanges to the longest sides of the plates, these flanges being turned downwards. Two holes are punched through the plates to correspond to those of the cast iron chairs for the bolting or fastening of the said chairs; a piece of wood about 4 in. thick is inserted betwixt the plate and chair, and they are bolted fast together. This wooden sole must be of the same size as the seat or sole of the chair, or a little longer. Two chairs, adjusted in the same manner, are connected together by means of a flat iron bar of a suitable thickness, and the required length for the breadth of the way. *Patent completed.*

1390. T. K. MACE. *Improvements in guards or protectors for hats and other coverings for the head.* Dated May 9, 1862.

This invention consists of a guard or protector for retaining the hat or head covering when by wind, accident, or otherwise it is removed from the head, the said guard or protector being used in place of the cord commonly used for the same purpose. In making a guard or protector, according to this invention, the patentee takes a small flat circular box similar to that of a measuring tape, the said box having a reel in its interior on which is wound a tape and or other flexible line. The reel may be turned so as to wind or unwind the tape, cord, or line, either by a winch on one end of its axis, or by fixing one of the circular sides of the box to the said axis, or to the reel, and making the said side capable of rotation. Or the reel may have a coiled spring by which the tape, cord, or line is wound up when its end is loosed, as in the spring measuring tape. *Patent completed.*

1391. W. EDDINGTON. *Improvements in portable grinding, chaff-cutting, and corn-crushing machinery.* Dated May 9, 1862.

This invention consists, 1, In fixing a grinding mill and a chaff-cutter, with or without an oat or a bean crusher, on one framework mounted on travelling wheels. By suitable gearing and clutches attached to the main driving shaft, either one machine or all may be worked at one time by means of a band passing round a rigger fixed to the main shaft, or by any other suitable way of deriving the power from an engine. The invention consists, 2, In so placing a lever to bear on the top of a spindle fixed to or connected to the centre of the top running stone that, by applying a small weight or spring balance to the longer end, it may cause the top stone to press hard on the lower one. *Patent abandoned.*

1392. F. F. B. MAYALL. *Improvements in dyeing mixed or plain fabrics and yarns.* Dated May 9, 1862.

In carrying out this invention, the inventor dyes mixed fabrics or yarns, such as a mixture of silk, cotton, woollen, worsted, and linen, at one operation, either black, drab, claret, brown, olive, and other colours, in not more than one to three vats, as may be required; or he dyes fabrics made of any one of the said materials separately in the same way. For this purpose, instead of using a number of vats, and, consequently, a number of separate processes, as at present adopted, he never exceeds 3, and in all ordinary cases, only 2; for example—in dyeing either mixed or plain fabrics black, in No. 1 vat, he uses chipped or ground logwood, brown sugar of lead, manganese, and ammonia of copper, with a little fustic chipped or ground. The heat of the water, and the proportions of the different materials used, must vary according to the substance of the articles to be dyed. No. 2 vat, which is a finishing or cleaning process, is composed of a solution of neutral chromate of potash, and bichromate of potash added if necessary, or for some shades a little ammonia or sulphur of iron. *Patent abandoned.*

1393. J. F. BLAND. *An improved method of, and apparatus for, signalling between targets and shooters.* Dated May 9, 1862.

This invention consists in the employment of an index or scale set in front and below the base of a target, at a convenient distance therefrom, say twenty yards, the numbers thereon corresponding with lateral divisions on the target, and in the employment of an indicator, consisting of a rod carrying a disc, numbered to correspond with vertical divisions on the same. To indicate the point at which the bullet strikes the target, the indicator is raised vertically by the marker at the number on the index, No. 3, for example corresponding with the lateral division on the target where the bullet has hit, and to such a height as to show a number 1, 2, 3, as the case may be, corresponding with the vertical division on the target in which the bullet has hit. To apply these signalling apparatuses, the inventor prefers to form a pit or excavation in front of the butt, so as to allow the indicator to appear above the ground, which is roofed over, leaving a space open in front. The index or scale is fitted on a level with the base of the target, and corresponding with the divisions thereon as before described. The earth is shelved off round the pit to throw water off. When the shooting is not being carried on, he covers the pit entrance, an open space as already described, and the pit with wood or otherwise. *Patent abandoned.*

1394. T. FAWCETT, JUN. *Improvements in plated fabrics for shirt fronts and other uses, and in the mode of mechanism for manufacturing the same.* Dated May 9, 1862.

This invention relates to improvements in shirt fronts and other plaited fabrics, and consists in producing, instead of the rough uneven fabrics hitherto produced for shirt fronts and other plaited articles of the same character, a smooth and even fabric, containing, however, the same quantity of warp in the parts intended to be exhibited when in wear, giving the cloth a better and more uniform appearance, costing much less, and being much better adapted for its purpose than fabrics made according to the methods heretofore practised. *Patent completed.*

1395. J. OXLEY. *Improvements in apparatus for facilitating the process of washing and sparging in breweries and distilleries.* Dated May 9, 1862.

This invention has for its object the raising in temperature of the contents of the mash tun by drawing the wort from the bottom thereof, and conveying it to a pan or receiver where it is heated by steam, and thence discharged through the sparger (specially constructed), over the grain contained in the tun. *Patent completed.*

1396. T. WELTON. *Improvements in the preparation of beverages in connection with brewing.* Dated May 9, 1862.

This invention relates to the manufacture of a new series of beverages or drinks. The base is to be of beer or ale brewed in the usual manner of malt (but the inventor prefers pale malt), with or without hops; he then mixes or flavours the same with the vegetable juices, syrups, or flavourings extracted or expressed from fruits or dried fruits.

These fruit juice flavourings may be mixed either at the time of mashing the malt, or afterwards, as at the time of fermentation, or after fermentation has ceased. The fruits he prefers are cherries, raspberries, strawberries, and pine apples; and of dried fruits, raisins, prunes, and figs. By this invention he manufactures beer or ale flavoured with any desired fruit, thus producing a series of new beverages or drinks. *Patent abandoned.*

1397. N. SYMONS. *Improvements of all kinds of wheels, framework, girders, columns, and stauncheons, blades of blowing fans, and paddle-wheels for steam-vessels.* Dated May 9, 1862.

This invention (which cannot be described without reference to the drawings) refers to a mode for a better distribution of all metals by means of corrugations, indentations, or grooves, or in any other form or shape that will increase the strength without adding to the weight, thereby equalising the expansion and contraction of the said metals. *Patent abandoned.*

1398. F. J. BOLTON. *Improvements in telegraphing for naval, military, and other purposes, and in the apparatus connected therewith.* Dated May 9, 1862.

This invention relates to a means of transmitting intelligence, or despatches, in broad daylight, by means of signals produced by flashes of light of long or short duration, or both combined. This object is effected by the employment of an intensely powerful light, consisting either of the electric light, the lime light, or other light, which is to be alternately obscured or eclipsed and displayed, so as to produce visible flashes of light of long or short duration, and in any desired order of succession, so as to produce the required signals. In combination with this light the patentee uses lenses, reflectors, or other well-known optical arrangements, in order to prevent the dispersion of the light, and to more efficiently concentrate or project it in the form of a pencil of rays of light upon the distant station or observer. *Patent completed.*

1399. F. J. BOLTON. *An improved mode of, and apparatus for, displaying the lights in lighthouses.* Dated May 9, 1862.

This invention consists in adapting or applying to the lamps or burners of lighthouses any convenient contrivance whereby the light may be alternately obscured and displayed at such intervals, and for such different periods of time as, by a pre-arranged system of signals, will indicate a code, number, or the name of the lighthouse, so that the latter may be instantly identified. These signals are to be repeated continually at regular intervals, so that the mariner, when at sea, will (upon coming suddenly upon this light), be able at once to know what is the code, number, or name of the lighthouse, and may therefore ascertain his exact locality without risk of making a mistake. The obscuration of the light may be effected by rising and falling shutters, discs, or other analogous contrivances, actuated by clockwork or other mechanism, or by means of an opaque cylinder perforated in a suitable manner to give the required flashes as it passes in front of the light, or as it rises and falls at the proper intervals. The system of flashes of long or short duration being pre-arranged to represent numerals or letters, the particular code, number, or name of each light will distinguish it from any other light. *Patent completed.*

1400. G. O. HASELER. *Improvements in lockets.* Dated May 10, 1862.

The patentee claims, 1, Making lockets of two loose and unconnected parts, as described. 2, Forming a recess or recesses on each side of a leaf or frame, with perforated or roughened backs, and securing or fixing the portraits or other designs thereon by means of cement, as described. And, lastly, he claims the application of a material known as "parkesine" as a substitute for glass in the manufacture of articles of jewellery. *Patent completed.*

1401. J. G. WILLANS. *Improvements in the treatment of the product from iron blast furnaces.* Dated May 10, 1862.

This invention consists, 1, In rendering pig or cast iron more conveniently malleable by causing an intimate intermixture therewith of unsqueezed puddled iron, or of crushed puddled ball or oxide of iron (alone or in combination), and causing the mixture to pass through and in contact with burning carbonaceous matters or gases, to which atmospheric air may be applied by a draught or apparatus. And also in collecting the fused metal in moulds passed before or under the tap-hole, consecutively, or having it sufficiently heated for amalgamation in a pot or reverberatory furnace. 2, In the abstraction of carbon from iron castings, by heating them in contact with a fused oxidizing substance, which consists of a metallic oxide (alone or in combination), not volatile, but fusible, at a lower temperature than the castings, such as may be obtained by the use of oxides of lead or iron. 3, In solidifying and rendering iron castings (whether more or less decarburetted or otherwise), more tough by compressing them out of the original moulds, as follows, viz, by applying the required pressure on some suitable substance surrounding the same (when heated or otherwise), capable of transmitting the pressure to the different surfaces of the casting without damaging its form, such substance being either gaseous, fluid, pulverulent, elastic, or compressible into shape. *Patent abandoned.*

1402. J. F. MILWARD. *Improvements in breech-loading firearms.* (A communication.) Dated May 10, 1862.

This invention cannot be described without reference to the drawings. *Patent completed.*

1403. W. CLARK. *Improvements in the application of a vegetable fibre alone, or in combination with other matters, in the manufacture of felted and other fabrics; also as a substitute for flock or powdered wool, and as a material for padding or stuffing, and for other useful purposes.* (A communication.) Dated May 10, 1862.

This invention consists in the employment of the down of the "Typha"—an aquatic plant—for the manufacture of felt for hats, shakos, police hats, and, when mixed with silk, wool, &c., for woven fabrics. *Patent completed.*

1404. R. MOORE. *Improved apparatus for indicating the presence, position, or accumulation of liquids, gases, or vapours, and apparatus for preventing danger or damage consequent thereon.* Dated May 10, 1862.

The object of this improved apparatus is to transmit from mines, holds of ships, tanks, and other enclosed, confined, or open places, signals indicating the presence, position, accumulation, or increase of liquid, gas, or vapour, mainly with a view to the adoption of timely measures for the exhaustion, circulation, diversion, exclusion, or removal thereof, to prevent or diminish danger or loss, and, in some cases, to put in action self-acting contrivances for effecting such exhaustion, circulation, diversion, exclusion, or removal. The means of transmission which the patentee employs for the purpose, and which he calls "transmitting media," consist of electric, electro-galvanic, or electro-magnetic currents of liquid, mercurial, or atmospheric pressure, of rods, wire, cords, or levers, or any combination of two or more of them acting on signalling contrivances—that is to say, on indicating dials, plates, or scales, or on bells, tympans, springs, or detonating or explosive contrivances, or other alarms, whether registering or otherwise. *Patent completed.*

1405. R. MOORE. *Structure and appliances of ships and other vessels.* Dated May 10, 1862.

According to this invention the patentee substitutes iron, or other metallic substance, corrugated either transversely, longitudinally, or diagonally, for the materials now usually employed in constructing or fitting up certain parts of ships or vessels. He employs apparatus for steering from below the water line without prejudice to arrangements for transmitting power from the deck, whether by the ordinary rudder or transverse screws. This he effects by rods, bars, or equivalent contrivances passed through stuffing boxes, or by wheels or chains working in water-tight cases or boxes, the said wheels, chains, rods, bars, or contrivances receiving their motion from the interior of the ship below the line of floatation. As an auxiliary in steering under certain circumstances he employs centre boards or plates, one at or near the bow, and another at or near the stern, so connected in their action that the lifting of the forward one and the lowering of the after one, and reversing, will make the vessel turn by her stern, and *vice versa*. He employs magnetic indicators for steering or laying the vessel's course, or correcting the magnetic variations of such indicators, or of the radiated card or table commonly called the mariners' compass. For this purpose, he uses three or more magnets, peculiarly secured or suspended in one instrument, but not necessarily in the same plane, and which indicate approximately the natural direction of the magnetic current. For cranes of ships, or other floating bodies loading and discharging, instead of the usual jib or derrick hoist, he constructs moveable travelling cranes, with rolling carriages, and other necessary adjustments, characterised by a system of levers, tilts, or lifts, by which the load is shifted in the desired direction for loading or discharging. He uses double or shifting shafts for driving propellers, and with the appropriate gearing and appliances therefor, and he connects the propeller to such shafts so as to be applicable for working partially below the line of keel or bottom of the vessel. He removes accumulations of water and dangerous gases and foul air from the holds or other parts of vessels by apparatus having projecting tubular or hollow arms or branches, the section of whose orifices is at right or oblique angles, or nearly so, to the axis of the column or conduit by which the gas, air, or water is raised or expelled, which arms or branches work in the fluid gas or air to be carried off. He employs, for ventilating ships or vessels, tubes varying in their application according to the direction to be given to the current of ventilation, but having for each circuit an induction and an eduction post. He uses gutta percha, caoutchouc, or other elastic or tenacious material, alone or in combination with other materials, as well as solid metallic or other substances, for filing, facing, coating, or lining corrugated metals used as before mentioned. *Patent completed.*

1406. J. T. COOKE. *Improvements in battens used in weaving.* Dated May 10, 1862.

These improvements consist of a new arrangement of driving planks for carrying the shuttles from side to side of their work, as hereafter described. The patentee uses two driving planks or bars, which are fitted with pegs in the ordinary way. One of the driving planks is sufficiently long to allow of a block being fixed on each end, so as to allow the other plank just to fit in between them, so that neither plank has any lateral motion apart from, or independent of the other. Or on one of the planks may be fixed a stud, to work in a slot in the other plank, sufficiently deep to allow of the rise and fall of each plank. The object of this arrangement is to secure the planks together, so that they both may travel the whole distance of the space and race, the motion being arranged in such manner as to allow them to do so instead of one driving plank taking the shuttle half its distance, and then standing still while the other plank takes it in the other half. The motion of these driving planks is cut and arranged in such manner that the driving plank in work carries the shuttle at work half its distance, and then falls from the shuttle sufficiently low to allow the peg to run under the piece or warp, but keeps travelling with the other plank at work, which rises into the shuttle at the same time the other is falling from it; the pegs are always either in the shuttles or just under the holes in which they work. The planks never stand in the middle, but traverse the whole distance from side to side with the shuttle, and thus prevent the jar and sudden motion of leaving one plank or bar at half the distance, and taking it up again in the return course. The invention is applicable to one or more tiers of shuttles. *Patent completed.*

1407. R. WILLOUGHBY. *Exhibiting and giving rotatory and traversing motion to placards, advertisements, scenes, &c.* Dated May 10, 1862.

This invention relates to an improved system of apparatus for exhibiting in public places and thoroughfares, within and upon the fronts of buildings, and other suitable places, advertisements, scenes, or other objects in a more efficient manner than is now performed. The improved apparatus consists of 3, 4, or more cylinders of any suitable length and diameter, placed in triangular, quadrangular, or other convenient position, and upon metal axes. Over these cylinders the inventor passes an endless band of cloth or other material, on which he fixes or places the object to be exhibited. He gives motion to one of the cylinders either by hand or power, and thereby imparts rotary motion to the rest of the cylinders. The endless band is guided by tapes and rollers of the number and size required by the length of the band, and the space or opening for the exhibition of the advertisements, or other objects. He also uses, when required, vertical supports made of metal or other material secured at intervals to the band, and to which he attaches pulleys; also a rail made of suitable material, along and upon which the endless band is caused to traverse through one window or opening in the building, along the front, and in at another window or opening. *Patent abandoned.*

1408. H. D. TAYLOR and E. ROBINSON. *Improvements in piece-dyed woollen fabrics, &c.* Dated May 10, 1862.

This invention consists in certain methods of producing blue selvages on piece-dyed fabrics, whether such fabrics consist of wool alone, or of wool mixed with any other fibre or material. *Patent abandoned.*

1409. J. HOUSE. *Apparatus for crushing or reducing substances.* Dated May 10, 1862.

This invention relates to a peculiar construction and arrangement of machinery or apparatus for crushing or reducing and working various substances, such as guano, grain, oil cake, clay, mortar, and cements. According to this invention, it is proposed to employ a pair of peculiarly constructed rollers, driven either at the same or different speeds, in relation to each other, by any suitable arrangement or gearing. These rollers may be either made in one or more parts, and composed of steel or chilled cast iron. In place of being cylindrical, they are formed on their surfaces with a number of alternate V grooves and projections of one roller working into the grooves of the opposite roller. These grooves and projections may be smooth on their outer surfaces, or they may have a series of teeth or notches formed on them with a view to the more effective reduction or disintegration of the substance under treatment. When these rollers are made in several parts, each part will consist of a disc having its periphery levelled on each side, so as to present a Λ or knife edge. By placing a number of these discs upon a square shaft, a roller of the description herein before referred to will be obtained, each disc being formed with a series of teeth or notches on its bevelled edge, or made smooth, as before described. *Patent completed.*

1410. W. H. RONALD. *Signalling and indicating the position of shots in rifle practice.* Dated May 10, 1862.

Under one modification or system of arrangement, the apparatus here employed consists of 1, 2, or other convenient number of arms, which are moveable upon an axis placed by preference below the ground. The arms are made of sufficient length to extend over the entire surface of the target, and they are fitted with sliding discs which traverse up and down the arms. At the extremities of the arms there are flags of different colours, denoting the different value of the hits; the discs are also provided with different faces, or discs of different colours and sizes. When a shot is fired at the target, and is to be signalled, the marker at the butt raises one of the arms by means of a cord passing over a pulley, so that the arm covers the spot struck by the shot. At the same time the disc is raised until it covers the part struck. The disc is allowed to remain stationary for a few seconds to enable the firing party to denote its position and record the shot. The disc is then allowed to slip down, and the arm is lowered in readiness for another shot. One of the arms carries the "danger flag," which is raised when required. In this way, during rifle practice, the shots are signalled on the exact spot hit on the target with ease, rapidity, and freedom from danger. *Patent abandoned.*

PROVISIONAL PROTECTIONS.

Dated July 18, 1862.

2056. R. A. Brooman, 166, Fleet-street, patent agent Improvements in generating heat in furnaces and fire-places. (A communication.)

Dated August 12, 1862.

2260. J. F. J. Leblond, Paris, machine maker. Improvements in sewing machines.

Dated Sept. 29, 1862.

Dated Oct. 23, 1862.

2855. W. Clark, 53, Chancery-lane, engineer. Improvements in sewing machines. (A communication.)

Dated Oct. 25, 1862.

2871. G. and W. Luke, 98, Mott-street, Birmingham, wholesale saddlers. An improved stirrup.

Dated Oct. 27, 1862.

2886. H. C. R. Joubert, upholsterer, 18, Maddox-street. An improved method of raising and fixing at any height desired music stools, chairs, or seats,

2889. T. Pilgrim, 17, Carlisle-terrace, Fairfield-road, Bow, engineer. Improvement in locks, bolts, latches, and other fastenings.

Dated Oct. 28, 1862.

2904. C. S. Duncan, Inverness-road, Bayswater. An improved compound or material for coating or covering metallic and vegetable substances to preserve them from corrosion or decay.

Dated Oct 31, 1862.

2950. F. E. Sickles, Bute-street, Brompton, engineer. Improvements in the means of steering and manœuvring ships or boats, and in the apparatus connected therewith which apparatus is also applicable for pumping and lifting weights.

Dated Nov. 1, 1862.

2954. W. Tarr, 112, York-street, Manchester, and E. Farr, 40, Cavendish-street, Oxford-street, Manchester. An improvement in pianofortes.

2956. M. and R. Merryweather, Long-acre, fire-engine manufacturers, and E. Field, Buckingham-street, Adelphi, consulting engineer. Improvements in steam fire-engines, part of which improvements are applicable also to other purposes.

Dated Nov. 3, 1862.

2962. F. Tussaud, 105, Marylebone-road, engineer. An improved machine for cutting metal, also applicable to cutting other substances.

Dated Nov. 4, 1862.

2982. P. W. Reuter, Buckland-crescent, St. John's-wood, merchant. Improvements in dyeing. (A communication.)

Dated Nov. 5, 1862.

2993. R. A. Brooman, 166, Fleet-street, patent agent. Improvements in commodes or water closets. (A communication.)

Dated Nov. 6, 1862.

3005. B. T. U. Monin, 60, Boulevard de Strasbourg, Paris, merchant. Improvements in breech-loading fire-arms.

Dated Nov. 7, 1862.

3009. M. A. F. Mennons, Paris. Improvements in the manufacture of paper. (A communication.)

3011. W. Clark, 53, Chancery-lane, engineer. Improvements in the means of utilizing refuse and azoted matters of commerce. (A communication.)

3013. T. Greenwood and J. Schofield, Rochdale, machine makers. Improvements in mules for spinning and doubling.

Dated Nov. 8, 1862.

3015. H. Gardner, Chapel-town, Leeds, engineer. Improvements in machinery for treating flax and other fibrous materials preparatory for manufacturing purposes, the said machinery being also applicable for pressing, rolling, grinding, pulverizing, or mixing various other substances..

3017. G. H. Ogston, Mincing-lane, consulting chemist. Improvements in treating nitrous acid and nitric oxide in order to convert them into nitric acid.

3019. W. Simpson, Liverpool, sorter. Improvements applicable to letter boxes and other like receptacles.

3020. G. L. Locke, Hampstead New-road, and J. Clark, High-street, Kentish-town, pianoforte makers. Improvements in the motive mechanism of pianofortes.

3021. E. Sonstadt, 3, Stewart-place, Alfred-street South, Nottingham. Improvements in the manufacture of the metal magnesium.

3023. J. Mellodew and T. Mellodew, Moorside Mills, Oldham, manufacturers, and C. W. Kesselmeyer, Manchester, warehouseman, Improvement in looms for weaving.

Dated Nov. 10, 1862.

3025. C. Connell, Glasgow, ship builder. Improvements in constructing ships or vessels.

3029. R. R. Holmes, British Museum. Improvements in folding chairs and seats.

3031. J. Shanks, Arbroath, machinist. Improvements in mowing machines.

3033. J. Easton, jun., and J. C. Amos, engineers, Grove, Southwark. Sawing wood.

3035. G. F. Lyster, engineer, Liverpool. Improvements in apparatus for elevating or otherwise transmitting grain and other granular substances.

Dated Nov. 11, 1862.

3037. W. Booth, J. Booth, and T. Booth, Oldham, mill-wrights. Improvements in rotary engines.

3041. F. Marriott, Miles-platting, Manchester, manufacturing chemist, and S. Holyroyd, manufacturing chemist. Improvements in the purification of gas, and in obtaining certain useful products therefrom.

Dated Nov. 12, 1862.

3043. W. and J. Galloway, Manchester, engineers. Improvements in machinery or apparatus for cutting, shaping, punching, and compressing metals.

3044. G. Smith, Phœnix Chemical Works, Cobden-street, Stewarts-lane, Battersea, practical chemist. Certain improvements in obtaining colouring matter.

3045. W. Dobson, Nottingham, lace dresser. Improvements in apparatus used in dressing lace or other fabrics.

3046. C. Socin, 2, Thavies-inn, Holborn. Improvements in looms for weaving ribbons.

3049. J. Faulding, 340, Euston-road. Improvements in locomotive engines.

3051. J. A. Duntze, Woolwich-common. Improved apparatus for communicating rotary motion to shafts or axles for various purposes. (A communication.)

Dated Nov. 13, 1862.

3054. G. W. Rendell, Newcastle-on-Tyne, civil engineer. An improved method of strengthening and hardening cannon made wholly or partially of carbonized iron or steel, or the barrels or other parts thereof.

Dated Nov. 14, 1862.

3068. W. H. Andrew, Sheffield, manufacturer. An improvement in scissors and shears.

Dated Nov. 15, 1862.

3084. F. Palmer, Northumberland-street, Strand, gentleman. Improvements in projectiles.

Dated Nov. 17, 1862.

3086. F. Rahles, Albert-street, Camden-road, professor of music. Improvements in envelopes, with the view to affording better security thereby.

3088. D. Thompson, Grosvenor-road. Improvements in screw cocks.

Dated Nov. 18, 1862.

3100. N. Thompson, 15, Abbey-gardens, St. John's-wood. Improvements in apparatus for stopping bottles, jars, and other vessels.

3102. J. Oxley, Frome, brewer's engineer. Improvements in apparatus for separating liquids from substances.

Dated Nov. 19, 1862.

3104. H. J. F. Marmet, 2, Rue Sainte Appoline, Paris. Some improvements in the construction of lamps.

3106. R. Mushet, Coleford, metallurgist. An improvement or improvements in the manufacture of cast steel.

3108. J. Arbós, Barcelona. Improvements in generating certain gases for obtaining motive power, and in the apparatus employed therein.

3110. C. Kilner, 2. Grove-cottages, Albion-grove, Islington, G. Kilner, W. Kilner, and J. Kilner, Thornhill-lees, near Dewsbury, glass manufacturers. Improvements in means or apparatus for the manufacture of glass.

3112. R. Hardman, Bolton-le-Moors, foreman. Certain improvements in looms for weaving.

Dated Nov. 20, 1860.

3116. C. Stevens, 31, Charing-cross. An improved brick-making machine. (A communication.)

3118. F. Fletcher, Birmingham, plumbers' brass founder. Improvements in the arrangement of a vessel or vessels for the compression of air as applicable to lift or force pumps.

3122. R. B. Seeley, Mortlake. Improvements in ink-stands.

3124. W, Bottomley, Bramley, Leeds, machine maker. Improvements in machinery for stiffening woollen and other fabrics.

NOTICES OF INTENTION TO PROCEED WITH PATENTS.

2056. R. A. Brooman. Generating heat. (A communication.)

2059. G. J. Yates and J. W. W. Tindall. Deodorizing paraffin.

2068. C. Ramsay. Military cloak.

2079. P. F. Cassegrain. Firearms.

2103. W. Clissold. Manufacturing cylinders.

2106. J. G. Clarke. Scythes.

2110. H. A. Jowett. Obtaining motive power.

2114. W. Clark. Decanting wine. (A communication.)

2117. V. Manzini. Locomotive engines.

2124. J. H. Selwyn. Paying out and raising electric telegraph cables.

2133. T. A. Favrichon. Baking ovens.

2140. H. Hedgley. Lamps.

2141. E. Burnett. Cart and sleigh.

2143. C. W. Siemens. Gas engines.

2144. R. Thompson. Sewing machines.

2155. M. Henry. Obtaining fibrous materials. (A communication.)

2160. B. Bailey. Cutting chaff and other vegetable matters.

2180. G. Haseltine. Drying grain, gunpowder, and other granular substances. (A communication.)

2199. W. Clark. Purification of water. (A communication.)

2332. J. J. H. Gebhardt. Fastening for purses. (A communication.)

2242. W. Clark. Carriage for conveying sugar moulds in sugar refineries. (A communication.)

2283. G. Welch. Inkstands, metallic pens, and pen-holders.

2531. J. Pender. Hoops for fastening bales.

2768. D. and C. J. Reid. Manufacture of cases for watches.

2861. J. Field. Steam engines, condensers, and boilers.

2938. H. L. Corlett. Construction of tuyeres.

2950. F. E. Sickels. Steering and manœuvring ships or boats.

2956. M. Merryweather, R. M. Merryweather, and E. Field. Steam fire engines.

2961. J. Winter. Tap or cock.

2971. D. Scattergood. Circular frames for the manufacture of looped fabrics.

3035. G. F. Lyster. Elevating or transmitting grain.

3046. C. Socin. Looms for weaving ribbons.

* 3052. A. Graemiger. Looms.

3060. R. and P. Sykes. Fibrous materials.

The full titles of the patents in the above list can be ascertained by referring back to their numbers in the list of provisional protections previously published.

Opposition can be entered to the granting of a patent to any of the parties in the above list who have given notice of their intention to proceed, within twenty-one days from the date of the *Gazette* in which the notice appears, by leaving at the Commissioners'

LIST OF SEALED PATENTS.

Sealed November 28, 1862.

1625. P. U. Payras.	1684. G. B. Toselli.
1648. T. T. Lawden.	1688. E. Scheutz.
1657. A. J. Sax.	1692. G. Rydill.

NOTE.—Specifications will be forwarded by post from the Great Seal Patent Office (publishing department) on receipt of the amount of price and postage. Sums exceeding 5s. must be remitted by Post Office Order, made payable at the Post Office, High Holborn, to Mr. Bennet Woodcroft, Great Seal Patent Office.

THE
MECHANICS' MAGAZINE.

LONDON, FRIDAY, DECEMBER 12, 1862.

THE SMITHFIELD CLUB SHOW.

THERE are not many novelties in the agricultural engineering line in this exhibition. Indeed, many of the "exhibits" have been transported direct from Kensington to Islington. The greatest novelty of the show consists in the building itself—a great improvement on the old Baker-street Bazaar. The available space in the Islington Agricultural Hall is no less than three times greater than at the former place. The spaciousness of the structure even produces the illusion that there are fewer exhibits of cattle and implements than there used to be in the Baker-street building. The company that has leased the hall to the Smithfield Club limited the cost to £25,000. The architect is Mr. F. Peck, of Maidstone; the contractors, Messrs. Hill, Keddell, and Co., of Whitechapel. These latter gentlemen agreed to execute the work for £24,980, the highest tender sent in being £26,600. The façade of the hall is in the Italian style, variegated with coloured bricks. The arrangement of these latter seem to us to be rather questionable, giving a striped "zebra" kind of look to the structure. The front, next Liverpool-road, shows two lofty towers for ventilating purposes, and also a central entrance, near which are different offices for the use of salesmen, police, telegraph and post offices, &c. The other front, next Upper-street, has a central archway, and a shop on on each side, and shops are intended to be constructed up to the great hall, and to cover the entrance up with an iron and glass roof. The main hall is 384 ft. long, and 217 ft. wide. This is covered with a central segmental roof of 145 ft. span, and 76 ft. extreme height. The two other side roofs are of 36 ft. span, and are re-turned at the ends; they cover the galleries for the reception of implements below, two tons and upwards in weight. Adjoining the Cattle Show is the minor hall, for the show of pigs. It measures 100 ft. by 100 ft., and is covered with roofing similar to that over the side galleries. The iron pillars are hollow, forming drain pipes from the roof to gutters underneath. There are five sets of double staircases, 10 ft. wide, leading up to the galleries. There is a reservoir above, containing 50,000 gallons of water, with hydrants to different parts of the building. There are three lines of stands on the galleries, one being against the wall, the other two being placed back to back down the middle. There are thus two clear lanes for the visitors, and a view of almost the entire hall can be seen from the balconies. The ventilating towers did not seem to us, on Tuesday evening, to quite fulfil their function, as it certainly felt rather close and hot in the galleries. The lighting up seems also rather deficient, although it is said that the number of gas-burners has been increased to 4,000, the number being 1,000 in the original estimate.

As to the living exhibits, shown in this, on the whole, very satisfactory structure, we must leave them to the consideration of other and better judges than ourselves. After being transformed into beef, mutton, and pork, we might, perhaps, hazard an opinion. We have certainly heard of pigs in connection with steam-boilers. The Yankees sometimes tell a story of pigs being thrown into the boiler furnace during the excitement of a Missisippi steam-boat race. We do not think that English pigs would run this risk.

"Like any other Englishman," we also imagine ourselves to be a judge of horse-flesh, but there were no cattle of this description entered by the Smithfield Club. Mr. Richard Roberts, the "Admirable Crichton of Mechanical Engineering," was accustomed to tell his pupils at the Atlas Works in Manchester, that the finest lines in Nature were those to be seen in a thorough-bred horse. This gentleman, in the varied machines he turned out while in practice as a mechanical engineer, was not satisfied with inventing the mechanical arrangements. He also strove to make every machine a work of fine art, by the elegant shapes and curves he gave to the main parts. Beauty and efficiency seem always to go hand in hand together, and the result is that he and his pupils have turned out some of the handsomest and best machines ever made in a workshop. There is a field also in this direction for implement makers.

As a result of the minute comparisons afforded by the long stay of the implements in the International Exhibition, we are inclined to believe that several improved plans, patented and otherwise, are getting into more general introduction.

It is a trite remark, that if the different patented plans could be combined into one machine, the general result would be greater excellence. This, we venture to say, would be more especially the case with the thrashing machine, avowedly in its present stage a very complicated and incomplete apparatus. One little fashion, we may notice, consists in the extended adoption of a grey drab-coloured paint for the portable engines. This tint harmonizes very well with the bright iron work. The exquisite locomotive engine of Beyer, Peacock, and Co., in the western annex, and the stationary engine of Ransomes and Sons, in the eastern annex, were painted in this manner. We understand that the Americans are using this grey tint for their war-steamers, as it makes a vessel less visible, and a more difficult mark for shot. Most, if not all, of these inventions have been described in former numbers, so we need not, while alluding to them, enter so much into details as we otherwise should do. If any manufacturer should take exception to the following remarks—remarks made in no unfriendly spirit—our columns are open to any communications he may wish to make in refutation of our assertions.

Taking a walk on the ground floor, below the galleries, catalogue in hand, we find that Messrs. TUXFORD & SONS, of Boston, are first on the list. They send three portable engines, and an old-fashioned looking stationary engine, the latter not being in the catalogue. One of the portable engines is a "10-horse power portable steeple engine," the cylinder being vertical, and with that peculiar old-fashioned not-at-all-to-be-admired arrangement of working parts denominated "steeple." We find it pompously stated in their trade circular that "the portable steam engine, with vertical cylinder, has clearly established the fact, so long maintained by Tuxford and Sons, that the upright position of cylinder is the true position for maintaining the power of the engine, and for producing in all respects the greatest amount of effectiveness with the least amount of wear and tear. These views have been supported by the Consulting Engineer of the Royal Agricultural Society." If Mr. Tuxford and Mr. Amos are right in this question, all the rest of the world are wrong. As was well noticed by Mr. Fairbairn, at the meeting of the British Association at Cambridge, and by Professor Rankine in his report on the Machinery in the Exhibition, the general tendency in all countries is towards the horizontal cylinder. Leaving locomotives, with their two horizontal cylinders, out of the question, we will venture to say that there are more horizontal cylinders in successful operation than cylinders in any other position. The antiquated bugbear of the weight of the piston wearing out a horizontal cylinder, has been disproved by the experience of the last thirty years. If an advantage is claimed for this engine on the score of its being boxed up from dust and dirt, we should say that the advantage is a very futile one. For one thing, it cannot be seen while at work. Besides, if covering up be so necessary, this can be done very easily with a horizontal engine. Mr. Tuxford does show two horizontal portable engines, so that he has made some concession to the prejudices of the multitude. If they have been made to order only, we should say that the customers have better taste than the maker.

SMITH, BROTHERS, of Thrapstone, send, amongst other things, a traction engine, which is on springs, a haymaker, and a chaff-cutter. The haymaker has the tines set on a cylinder in such a way that they cannot turn up more than a fixed size of swathe. The feed-rollers of the chaff-cutter have merely globular prominences, or round knobs, cast on them. These knobs appear of doubtful efficiency for bringing the hay up to the knives.

Messrs. GARRETT and SONS send an improved edition of the double-cylinder engine they had in the Eastern annex of the Exhibition. Their thrashing machines are distinguished by three blasts used in dressing grain, being taken from a single powerful fan placed outside the drum spindle. They have also some steam ploughing tackle, manufactured at their works, upon Messrs. Howard's principle. We wonder whether they will improve this tackle to the same extent that Messrs. Howard improved upon Mr. Smith's, of Woolston? Messrs. Howard seem to have improved Mr. Smith's invention off "the face of creation," as the Yankees say. The exhaust pipes on their engines seem rather diminutive. We believe that there is also a firm of this name near Magdeburg, in Prussia.

FERRABEE and Co. send some engines among other exhibits. The cutters on the connecting rod end of these engines are adjusted in the same way as the jaw of their universal spanner. The double cranks of these engines seem too far from a proper bearing.

HORNSBY and SON's thrashers are of rather novel make. The straw shaker and vibrating board cranks are made in parts, that the bearings may be renewed when worn. We believe that the drum has Wallis and Haslam's patent spherical bearings. There is only one belt used. Their improved corn elevator consists of a kind of Jacob's ladder, but instead of the cups, plain plates are fixed on the belt. It also (we presume from its high speed) acts as a barley awner and chob cleaner. This apparatus is probably one of the results of the impulse given to improvements in thrashing machines by that remarkable invention, or rather discovery, the Bruckshaw and Underhill Elevator. We doubt, however, whether it will act so well as the latter contrivance. The turnip-cutters and the root-pulpers exhibited by Hornsby and Son form, we believe, a new line of trade for this firm, and are shown for the first time. Both the turnip-cutter and the root-pulper are made out of a revolving disc, as in some other similar machines. The turnip-cutter has angle knives (known as Gardner's) fixed on a curved bar, so that the knives cut into the root one after

another. There is a flange on the disc, the function of which is to return the "last piece" to the feeding hopper, to get properly cut. The pulpers have single diamond-pointed knives of steel, all fixed with wooden wedges. The machines are fitted with an oscillating bar, having teeth, through which the cutters pass, and worked to and fro by a 3-16 throw eccentric, which is placed on the main spindle. This arrangement is to prevent the escape of the last piece and to clear the cutters. The crank shaft brackets of the portable engines are cast in the shape of two "classical" (!) columns, which arrangement, we suppose, is considered "high art" at Grantham.

Messrs. Tasker and Son, who style themselves "general engineers," send, besides other implements, a thrashing machine fitted with Underhill's elevator.

Mr. Foster, of Lincoln, sends an 8-horse engine and a thrashing machine. We took the engine, at first sight, to be one from the Stamp End Works. It deserves great praise for exactitude, as it is a correct copy of the Clayton and Shuttleworth engine. "Imitation is the best flattery," and no doubt Mr. Shuttleworth feels highly honoured at his plans being so carefully followed. The exhaust pipe is taken back through the boiler, as in the Stamp End products, but it has not the strong hollow castings for crank-shaft brakets, which distinguish the latter. The thrashing-machine has a chob-cleaner, placed so as to lift up the grain from the chob-spout to the Jacob's ladder elevator, which latter is thereby somewhat shortened.

Burgess and Key send M'Cormick's sheaf delivery reaper, the very same highly-ornamented article shewn in the American Department of the International Exhibition. They also show several chaff-cutters, very similar to the well-known ones of Richmond and Chandler.

Mr. John Fowler exhibits his large steam ploughing tackle, in the shape of a large engine and four-furrow balance plough, and ditto cultivator. We hoped to have seen Mr. Fowler's new plan, with slack gear, for using an ordinary portable engine in a direct acting way. We suppose that the sale of a large tackle would pay better. We consider that Mr. Fowler is a public benefactor, from the amount of money and brains he has invested in steam ploughing. He has our hearty wishes for his continued prosperty.

Messrs. A. and E. Crosskell show the Victoria reaping machine amongst their exhibits, the same machine introduced into this country by Messrs. Ransomes and Sims.

Brown and Co., Cannon-street, show a compact little specimen of a one-horse engine, some lawn-mowers, hurdles, iron gates, &c.

Clayton, Shuttleworth, and Co. send a number of their well-known engines and thrashers, We alluded at some length to the former exhibits in our last week's number. We expected to see some of these portable engines with the fire-box flush with the boiler-barrel, but are disappointed. Their traction engine is an improved edition of the remarkable specimen of mechanical engineering they sent to the Great Exhibition. The reversing gear does not consist, at present, of a screw with a *slow* pitch (!), but of a reversing handle and link, both of which are absurdly cranked and twisted. Their thrashing machines have, of course, Underhill's elevator. They have also, for a number of years, been the users of Goucher's patent beater. A report as to the results of Mr. Goucher's application for a prolongation of his patent will be found further on in our columns. Considering that all the patented beaters out are evasions, more or less, direct of Mr. Goucher's patent, he has fully deserved to have his patent prolonged. We believe that, naturally enough, Messrs. Clayton and Shuttleworth opposed the application.

W. S. Underhill shows a thrashing machine with his patent elevator. This, as is well known, consists simply of an ordinary fan, revolving at about 500 revolutions per minute, and into which is fed the grain to be elevated. It throws up the grain through the blast, the centrifugal force, and percussive action of the blades, combined. It also chobs wheat and awns barley at the same time. It is a remarkable invention; and is, no doubt, in its further developments, destined to form an era in the improvement of the thrashing machine.

Messrs. Howard show their well known horse ploughs and steam ploughing tackle. In the latter, as is well known, they devote themselves exclusively to the use of the ordinary portable engine.

Messrs. Nalder and Nalder show several of their well known screens, and a complete thrashing machine, the latter at a very low price. The screens are made of very thin cast-steel wire, whereby greater screening surface is secured to a given size. The wires are fixed into slits in the longitudinal bars of the screen, the bar being rivetted back into the wire. The finer wire, probably, does not adhere so tenaciously to the grooves as wire of a thicker kind would. All the reciprocating parts of the thaashing machine are suspended on elastic joints, on Coulson's principle; they consist of ash springs. This excellent plan seems to be getting into extensive use. Clayton and Shuttleworth are also adopting spring hangers.

Aveling and Porter send two of their excellent agricultural traction engines.

Coleman and Sons exhibit a traction engine made by Messrs. Clayton and Shuttleworth. We believe that this is the famous engine that would not come in at the gateway. A couple of timber uprights had to be removed before it could pass inside.

Holmes and Sons, of Norwich, show their thrashing machine, which is made so as to sack the chaff. The whole machine is made very low from the ground, and is thus rather convenient.

Ransomes and Sims send that great variety of articles which make this firm quite a "universal genius" in manufacturing. We alluded last week more particularly to their engines. Their thrashing machine is very well arranged, and the details about it are very good; indeed, we should be inclined to give it the preference over almost any other in the Show, although we believe that it costs £10 more than any other. The beater drum is a modification of Goucher's, the beaters being made of three-sided wrought iron rods, twisted while hot into the form of a screw. It must be rather heavier than its prototype, but that is by some considered an advantage. The shakers are peculiar, being those known under the name of Brinsmead's rotary shakers. It consists of a series of revolving rollers, each armed with three rows of spikes. The spikes nearly touch the circumference of the adjacent rollers, and also the *fixed* board forming the bottom of the straw shaker. The straw is thus shaken forward, while the cavings are urged back towards the riddle. The screen used in their finishing machine is an admirably ingenious apparatus, the construction of which, however, cannot be made plain without a drawing. It can be adjusted to any size of grain. We will shortly describe it in one of our numbers. They also send a harrow, the teeth of which are fixed in a novel manner. We hope to be able to illustrate this arrangement next week.

W. C. Cambridge sends his well-known chain harrows and clod crushers.

C. E. and F. Turner exhibit some engines, &c., which we believe also figured in the Exhibition. The piston-rod of one of these engines seemed very weak. Perhaps it is of steel.

Woods and Cocksedge show what they call a chaff-sifter. It consists of a neat arrangement for giving motion to a large sieve. It does not appear in the official catalogue.

Mr. Collinson Hall exhibits, close by, a steel-link chain, working on a seven-sided drum, as a substitute for a wire rope. If there were no such a thing as steel wire rope, this would probably be an improvement.

Ashby and Co. have sent their rotating harrows, an American invention, we believe, which we have also described in a previous volume. Their beater is another modification of Mr. Goucher's.

Brown and May make an appearance with their portable engines. They are properly balanced by a counterweight being cast into the rim of the fly-wheel. The counterweight might, however, have been made more shapely. There is a deflector for coal-burning placed on the fire-box door of the 8-horse power portable engine. Near this stand is a working model of a pump, with very ingenious valves, invented by Mr. Holman. We hope to be shortly enabled to give a description of this.

Barrett, Exall, and Andrewes, send their rather slimly-proportioned engines. They have made the fire-boxes of their portable engines flush with the boiler barrel, and are thus in advance of most other makers. We like the general arrangement and the details of these engines. Their thrashing machines have Underhill's elevator, Coulson's spring hangers, and Wallis and Haslam's spherical bearings for the beater drum.

Ruston, Proctor, and Co., send another younger brother of the Stamp End shape of portable engine. The exhaust pipe is carefully taken through the boiler.—Humphries, of Pershore, have an old-fashioned style of thrashing machine in the Show.—Robey and Co. exhibit their 10-horse traction engine. It is on springs, which is an improvement.—Davy, Brothers, Sheffield, have arranged the eccentric rod of their engine on a skew, with the centre line of same.

Allchin and Son exhibit engines with not very commendable details. They use superheated steam. It is passed through pipes in the smoke box.—Marshall, Sons, and Co. "limited" show another engine of the Lincoln "Stamp." Is it the scheming that is "limited" in this firm?—J. and F. Hancock make an appearance with a number of their pulverizer ploughs and butter machines. The pulverizing plough seems to us to be a very clever idea. It is a pity that the detail and the workmanship is not of a better quality. In the hands of a Howard, a Hornsby, or a Ransome, it would be a very different tool. We hope next week to be enabled to resume our notice of the exhibits in the gallery of this temple of agriculture.

TT.

HOW TO IMPROVE THE QUALITY OF CAST AND WROUGHT IRON.

We lately felt constrained to speak in terms of unqualified praise of the new edition of "Truran's Iron Manufactures of Great Britain." A more minute analysis of the work has served only to fortify us in our first position in regard to it. It is replete with practical and reliable information on the sub-

ject of which it treats, and is worthy a place in the library or on the office-table of every mechanical man in or out of Great Britain. Perhaps there is no consideration of more real importance to the founder, the engineer, and the general mechanist than the means of improving the quality of iron. It is a point upon which it is not possible to lay too much stress, and it is very properly made a prominent feature of in Truran. Many modes of improving the quality of bar iron, by the addition of various metals or oxides at one or other of the stages of its manufacture, have been devised. In all propositions, however, for the improvement of malleable iron, by the incorporation therewith of foreign ingredients, it should be borne in mind that while it is possible to improve thereby a single characteristic, the inevitable result is to lower the general quality of the iron so treated. In seeking to improve the general quality, it should be distinctly understood that a *bonâ fide* improvement can only follow the abstraction of an injurious alloy, the substitution of a less for a more injurious mixture, or from the addition of a metal superior to that of the iron under treatment. Under no circumstances whatever can the mere addition of substances, or metal of superior qualities, improve the general qualities of iron. These are heightened and developed by every degree of refinement, but inevitably debased by every adulteration. The list of substances capable of being mingled or alloyed with iron is large, but their employment as a means of improving the general quality is invariably attended with contrary effects. The presence of carbon, by lowering the temperature of fusion, increases the fluidity of cast metal; but the qualities of hardness and tenacity are reduced in nearly the same ratio. Silicon in quantity seems to impart additional hardness, but induces a deficiency of tenacity, and materially impairs the ability of the metal to withstand crushing and abrading forces.

The tenacity of cast-iron of a low specific gravity, and consequent inferior quality, may be improved by remelting and incorporating in it wrought-iron scraps of a superior tenacity. But the improvement in quality by this treatment nearly disappears when the cast-iron is of a high specific gravity. Any improvement occurring to irons of low quality, debased by the presence of an excess of carbon, is due mainly to the increase of density and greater purity which follows the partial oxidisation of the volume of carbon during the operation.

The superior strength of air-furnace castings is generally admitted by ironfounders, but the common explanation of that superior strength, of its being due to a greater degree of homogeneity, arising from the remelting of the crude iron, is, we think, altogether erroneous. The simple operation of remelting increases the density and tenacity of crude irons of grey quality in proportion as they are charged with carbon. Further remeltings develop those chatacteristics until the iron has attained a high degree of refinement, and increased its tensile strength hy one half. With white irons from blast furnaces, consuming a minimum quantity of fuel, the improvement is not so marked; and this arises from the fact that they contain a smaller amount of carbon, with a greater quantity of metalloids more difficult of oxydation. The remelting in this case is, therefore, attended by a larger waste of metal in proportion to the volume of impurity removed.

While maximum tenacity is attained only by remelting and mechanical subsidation, the operation results in a corresponding loss of fluidity, and the iron so treated is not adapted for small castings, or the filling of sharp angles or mouldings in larger. Iron undoubtedly possesses the greatest density and tenacity when pure, and the presence of any other metal or matter in mixture or alloy reduces its density, and diminishes in a more rapid ratio its tensile strength. Specific gravity and quality are, to our thinking, nearly allied in the character of irons, and weight is one of the best tests of quality. We shall return to this subject anon.

CHATHAM DOCKYARD.

The cost of these works for land defences are estimated at £1,350,000. They would mount 335 guns, and would require barrack accommodation for 3,550 men.

The "transformation of the navy," to use the euphemistic term in vogue for the substitution of iron for wood in the construction of men-of-war, has effected a radical change in the economy of Chatham Dockyard. The state of transition in which everything appears, the results of tantalizing essays that are to be met with here and there, show how great has been the change, and how laboriously it has been effected. Six timber ships are on the slips—the "Salamis," the "Myrmidon," the "Rundere," the "Belvidere," the "Berlinda," and the "Menia." On some there are perhaps half-a-dozen shipwrights at work on each; on the others none, and they are left to the care of a ship. Two covered slips of the most recent construction, by Gressel and Co., in 1856, are unoccupied, and from one of them, the "Royal Oak," now plating with armour in No. 3 dock, was lately launched. The timber-floating basin looks desolate, the mast houses abandoned, and the whole activity of the yard appears concentrated on the two armoured ships which are in the process of construction, and in the shops where their component parts and plates are being shaped and fitted.

Entering the yard we pass storehouses and workshops that give out no signs of life under the change, and the slips where a despatch vessel and other small craft are standing. Next is No. 1 dock, built for the reception of small vessels, but which has been covered on a level with the soil, and roofed over to serve as a fitting shop for the "Achilles" iron ship, which is building in the dock No. 2 alongside. It is here that the frame of the ship is prepared and fitted in parts before being built up. The frames, which answers to the ribs of timber ships, are composed of bars of angle iron, from ⅝ to 11-16ths of an inch thick, riveted together and bent into the desired shape. For this purpose a modern mould is made to each frame—that is to say, thin boards are sawn out to represent in their convexity the sectional lines of the ship. On the floor of the shop is the "levelling plate." It consists of massive iron blocks, pierced with numerous holes disposed quincancially, and solidly bound together to form a levelling plate of sufficient thickness. Opposite and close to one end is a pair of hot-air furnaces for heating the angle iron. They both communicate by flues with one chimney, and other arrangements are adopted to ensure an economy of fuel, as well as the uniform and quick heating of the bars of angle iron. The furnace itself is at the end opposite the door, and in one case there was a furnace in either of the longitudinal sides. The heat and products of combustion pass from the furnace over the brick bed on which the bars are placed, and escape by a return flue to the chimney. The brick roof being arched, throws down the heat upon the iron. When the bar has been raised to the requisite temperature it is withdrawn, and laid on the levelling plate, whereon the sectional line or form of the set has been previously marked by pins inserted in the holes of the levelling plate. Then with hammers, tongs, and hand-spikes, the bar is rapidly bent to the required form. The turning up of the portion resting on the plate is remedied by flat-headed punches, fastened to long withy handles, held by workmen, while others strike the punches on the head with huge sledge hammers until that portion of the bar is levelled. It cannot fail to strike the spectator that this mode of carving the frames is unnecessarily tedious, costly, and requires a degree of human labour unsuited to the inventive genius of the age—so fertile in contriving labour-saving machines. There can surely be no difficulty in devising a machine which would roll the bar to the sectional line in one operation, and in no more time than it takes to write this sentence. If a pair of rollers—one vertical to bear upon the portion of the bar resting on the levelling plate, and the other horizontal, to bear upon the upright portion behind, which are the pins—were placed in connection with a mechanical arrangement which would make them follow varying curves—an arrangement, in fact, something of the character of a pentagraph—then the operation would be simplified, and more expeditiously performed than now, when a dozen or fifteen men are required to bend a bar by dint of sledge-hammering, for then all that would be required would be a sufficient number of hands to draw the bar from the hot-air furnace by an overhead traveller, and to arrange the pins according to the curve, while one man at the other end of what, for lack of better name, must be called a pentagraph, would suffice to cause the rollers to travel in the curve of the sectional line, as will be easily understood. It matters not whether this or any other mode be adopted of rolling the bars of angle iron into any curve that be required; the essential point is to introduce machinery to shape the frames so that they may be more accurate, take less time in their production, and cost less money.

Each frame or rib is composed of two or more bars of angle iron, held together by "holler riveting," so as to support for the iron skin, teak-backing, and armour plates on the outside, and supports for the planking inside. The frames for the stem and stern are more complicated, and composed of a greater number of bars, but this system of construction is the same; the rivet holes in the frames are punched out by the ordinary machinery, and the rivets are hand-fastened while cold, and this, although Fairbairn claims for machine-riveting a superiority of from 4 to 5 over hand-riveting. When finished so far, the frames corresponding are temporarily fitted together, and the parts carefully adjusted; after which they are placed in the positions they are permanently to occupy—the ship being built in sections. The beams are of iron rolled into the shape of double flanged girders. The combination of angle iron undoubtedly gives frames of great strength, but still, to the eye, a thickness of ⅝ of an inch appears slight when we remember the enormous weight they have to bear of armour plates, teak backing, skin, and outside planking. True, the frames are very close, and so would compensate for their apparent slightness.

The next point of novelty and interest is the preparation of the armour plates and their fixing to the ship's sides. They are manufactured by the Thames Ship-building Company, and are said to be superior to all others in quality, homogenity, and toughness, that have been sent in from the great centres of iron manufacture. If so, and there appears no reason to doubt the statement, the fact is noteworthy, as showing how good workmanship will overcome the disadvantages of increased cost of labour, raw materials, and fuel. As compared with northern iron manufactures, the Thames Company pays double the price for fuel, a fifth more for wages, high rent, and the carriage on raw material; while from the north the carriage is paid on the manufactured product. To judge from their working, the plates are of an unusually excellent quality. Their weight averages 3½ tons, including the large ones for the broadsides, and the smaller ones for the bows and quarters. The thickness of the first is 4½ in., while the second, which present oblique surfaces to shot, are less.

The first step to putting on the ship's armour, above the iron skirt, bolted to the frames by hot rivets, and a teak backing, 8 in. thick, overlaying the skin, is to take a mould of the curved surface of that portion of the ship's side to which the armour plate is to be adapted. These moulds

are taken in thin planks for the horizontal and vertical curves—that is to say, for the curves to be given to long and short sides of the plate. A number of wrought-iron bars, longer than the width of the plate, of about 5 in. thick, and 3 in. broad, are bent to the vertical curves of the ship's side, which the plate is to assume, in order that it may fit closely to that portion which it is intended to protect. In front of a hot-air furnace is the bending cradle, which now first devised for shape the armour plates of the floating batteries constructed for the attack of Russian maritime fortresses during the late war. The cradle consists of two vertical and parallel open frames—pierced with numerous holes in the upper half—each of the length of the plate, and set apart a distance equal to the width of the plate. The open frames consist of a number of wrouht-iron slabs, somewhat more than 3 ft. high, 8 in. wide, and 1 in. thick. The space between each two is equal to that of the shaping bars. The slabs have a double flange at bottom, by which they are securely bolted, in a vertical position to the bed plate, and a flange on the inside at top, to which a longitudinal slab is bolted throughout the entire length, to give increased rigidity to the frames, and at the same time to serve as *point-d'appui*, against which wedges are driven to force the armour plate down. At about the centre is another longitudinal slab, on which the ends of the shaping bars rest, and which is capable of adjustment, to give the required curve to one side of the plate. The longitudinal slabs, and cross or shaping bars, being arranged according to the mould taken from the side of the ship the armour plate is to cover, the latter is withdrawn red-hot from the hot-air furnace, opposite and close to one end of the cradle, and laid upon the shaping bars. Immediately other bars are introduced above the plate, but below the longitudinal slabs, and with their ends passing beyond the spaces between each two of the vertical slabs. Wedges are next driven in between the tops of the upper bars and the bottom of the longitudinal slabs, until the armour plate is bent down to the curve required. The driving in of the wedges is tedious and laborious in the extreme. On either side of the cradle are iron rammers, weighing each about 600 cwt. They are balanced and suspended from the centre by chains attached at top to rings, which are free to travel along horizontal iron rods over head. The rammers are worked by men horizontally in pairs, and against the wedges over the ends of the same bar simultaneously, so that the plate may be forced down gradually. Were all the rammers worked at the same time, as they should be, and with a minimum of four men to each, it would require twenty-four men to bend a plate in one heating. If this be persisted in, which we do not think likely, there is no reason why the wedges should not be driven in by moveable steam hammers, working in a horizontal plane.

The inventive facilities of our engineers are surely equal to devising some mechanical means to bend the armour plates, whereby human intelligence will be all that will be required to direct the force of steam. Whether it be by steam hammers travelling over the armour plate laid in a compound bed plate, capable of being adjusted to the required curve, only adjustable rollers passing over the surface of the plate, in manner similar to the one above, or by a series of hydraulic presses with adjustable surfaces, that the problem will be solved, we know not, but we feel confident that it will be solved, and are strengthened in this belief by the fact, that an invention made at Plymouth for effecting this object, by a series of hydraulic presses, and that an officer of the Admiralty has been despatched to examine and report upon it. However, the system of shaping cradles, which was employed to bend the plates of the "Warrior" and "Resistance," admits of the plates being bent to within ¼-inch of the required curve. Since the "Warrior" was plated, further advance has been made to accuracy, and the plates are now curved to fit quite close to the ship's side. For this purpose the plate, after it has been in the shaping cradle, is removed to a hydraulic press of peculiar construction, made by Messrs. Westwood, Baillie, and Co., and capable of increasing a pressure to 2,000 tons. The bed plate, so to speak, is carried above the piston by two pairs of stout cylindrical standards, having screws cut on the upper parts and fitted with nuts to admit of the bed plate being adjusted to any required height. The armour plate (cold) is carried in slings when not resting on stout wooden rollers; two on either side of the press, whereby it is shifted to and fro between tha bed plate and piston. The workman is provided with moulds exhibiting the curves to which the plate is brought. Then, by blocks and sheet iron of various thicknesses, which he places between the armour plate and bed plate, he blocks up the first to the required curve, using the portion of the hydraulic press to bulge out the plate, as it were. After this the plate is carried to a horizontal planing machine, where the longitudinal sides are placed to obtuse angles, one entering and the other projecting, so that the plates may fit accurately to one another and hold fast together. The "Warrior's" were, we believe, tongued and grooved, and plates of this form may be seen in the yard; but the arrangement of angulated edges is undoubtedly the best. The ends of the plate are planed straight in vertical planing machines, and particular holes on two ranks are drilled in the plate if it be of the largest size. Instead of being cylindrical, the holes are conical, or diminishing in diameter from the outside to the inside, so that a considerable amount of the strain is transferred from the heads of the bolts, which are countersunk, to the whole of that likewise conical which holds in the thicknes of the plate. Then the plate is carried on a horse to the side of the ship, where it is lifted by a pontoon steam crane, which travels fore and aft on a tramway alongside the deck, each on one side. In this position the inside of the plate is daubed over with red paint, and then lowered on to spars or inclined guides, down which it slides, and is applied to the part it is to protect. Afterwards it is removed to ascertain from the marks left by the red paint if it fits accurately. If it does not—and it very rarely fits the first time—the plate is carried back to the hydraulic press to be operated on again and again until the exact curve is attained. When this is done, the plates up to the walls are coated on the inside with tar, and fixed to the ship's sides with tarred felt. Above the walls, dry felt is used, and the plates are not tarred. The bolts which hold the plate are 1½ in. in diameter, and look too slight to hold so great a weight as they will have to do in a rolling sea. But when it is remembered that Mr. Edwin Clarke deduced, from experiments made in connection with the Britannia-bridge, that it would require 24 tons to shear a rivet of 1 square inch sectional, it will be seen that the bolts which have a sectional area are nearly double; 1·76 in. are ample. Mr. Fairbairn gives something less; but taking the very minimum, there can be no fear of the plates shearing or dragging the bolts unless the elasticity of the timber back should, in the course of time, allow of too much play. The bolts are provided with screws on the inside, and nuts, so that the plates could be tightened. Nevertheless, the system of fastening receptacles is the weakest point in the whole method of construction. Both the "Achilles" and "Royal Oak"—the iron and timber ships—are plated in the same manner, and certainly nothing can surpass the workmanship. The plates are close home, and fit to one another with the greatest accuracy. They require no caulking or cement to hide the seams, like the "Warrior's." Plated from stem to stern, these new ironsides are a great improvement on the "Warrior," and their sides as smooth and sightly looking as any timber ship, with the exception of the sterns. The stern of the "Achilles" is not yet up, but that of the "Royal Oak" is as ugly as it is possible to imagine. It resembles nothing so much as the stern of a dummy at any of the landing piers on the river. It doubtless has its use, though it must prevent fire from the main deck in the same vertical plane as the keel—a faculty not to be despised in a stern chase. What makes the workmanship of the plating so noteworthy is that it has been executed by shipwrights. Some time back the engineers, to the number of 90, struck work. They were allowed to go, and their place supplied by shipwrights, who were doubtless glad of the chance, for they saw their trade threatened with extinction, consequently they took to their new trade with a will. In a couple of days they could drive rivets as fast and as well as a regular boiler-maker, and they may be now seen sledge-hammering, punching, drilling, planing, and shaping iron, as if they had never done anything else all their lives. The lesson is a useful one, both for men and employers. It shows that among intelligent workmen the division of labour need not preclude the attainment of proficiency in several branches of handicraft by the same individual.

The stern-post of the "Achilles" is a magnificent forging, and a marvel of Cyclopean working in iron, but its very massiveness and weight fills the visitor with apprehension for the safety and durability of the ship to which it is to be fixed. Placed at the extreme end of the keel, and as far as possible from the fulcrum, it must exercise great leverage, and shake the ship terribly in foul weather. So forcibly does this idea take possession of the mind, that one is disposed to ask whether it would not be possible to build the stern-post cellular fashion, of thick plates riveted together, and stiffened by stays and braces inside; or whether it is absolutely necessary the stern-post should be rectangular in construction; might it not be cylindrical, and constructed after the fashion of Captain Berkeley's guns—*i.e.*, of tubes shrank in one over the other until the requisite strength and stiffness are obtained?

It will be seen, from what has been previously stated, that Chatham has only four docks, and virtually only one, since three of them are occupied by ships in construction. To remedy this deficiency new docks and a basin are to be constructed in Wellary's Island, of which we hope to be able to give an account very shortly.

MOMENTUM AND VIS VIVA.

When we consider that eminent scholars have taken different views upon the measure of the force in a moving body, it is not strange that students, while yet in the elements of mechanical science, should be at a loss to know whether the force varies as the velocity or as the square of the velocity. They do not see why the momentum does not express the force as well as the *vis viva*; or they fail to distinguish between the nature of these two forces; or they do not get a very clear conception of either.

It is not our purpose in this article to enter into a discussion of the measure of force, but to try to show clearly to students the nature of the above named forces by showing the office which each performs in the same moving body.

Vis viva, sometimes called "living force," is a mere conventional term to express the product of the mass of a body multiplied by the square of its velocity. It bears a direct relation to the *work* which the moving body is capable of doing; being just double the work. For whatever be the work which it does, or is capable of doing, we know that the same amount of work may be expended in raising a weight through a sufficient height.

Let W = the weight.
h = the necessary height.
M = the mass of W.
V = the velocity required in falling through h.

Then it is well known that $W h$ = the work done. But from the law of falling bodies,

$$V = \sqrt{2 g h}, \text{ or } h = \frac{V^2}{2 g}.$$

$$\therefore W h = \frac{W V^2}{2 g} = \tfrac{1}{2} M V^2$$

But $M V^2$ = the living force; hence the wor

which a moving body is capable of doing is one-half the living force, or *vis viva*, of the body.

To work is to overcome resistance; hence a body may move and do no work. The fact that it has mass and moves, is evidence that it is capable of doing work; and if it changes its velocity it either performs work or has work expended upon it.

The force which is stored in a moving body is a force of inertia; hence it is equivalent to the force which would cause the body to move from a state of rest to a velocity V, when free to move without any resistance. We see, then, that when a body is moved against any resistance—as air, water, or friction—that the force which would give the body a velocity V, may be divided into two parts: 1st, that which directly overcomes the resistance of the air, water, and the like; and, 2nd, that which overcomes the inertia of the body; and it is by knowing the terminal velocity and the mass that we are able to tell the amount of resistance (in lbs. feet) that the body would overcome without applying to it any additional force.

Before developing this idea further, let us turn our attention to the subject of momentum. Momentum is also a conventional name for the expression $M\,V$. If we were permitted to call it a force, we would say that it is also a force of inertia. It is also called "quantity of motion;" for by knowing the masses of two bodies, elastic or non-elastic, and the velocity of one before impact, we can find their velocities after impact; bodies being supposed to be free to move.

Now, in order to show the office which each performs in moving bodies, let us take a few examples.

Suppose two perfectly non-elastic bodies of equal mass (and consequently of equal weight) move with equal velocities in opposite directions; what will be their condition after impact?

Now, because their *momenta* are equal, we know that they will destroy each other's motion, and hence, so far as their motion is concerned, they will be in a state of rest. And this is all that we can determine from the principle of momentum. It relates to the motion of the masses. But, as a fact, we know that before they came to rest there was a compression of the two bodies, and hence work was done. The amount of this compression depends upon the *vis viva* of the two bodies. By momentum we decide that the bodies will come to rest, whatever be their velocities, provided that they are equal; by *vis viva* we decide that the amount of compression is directly proportional to the square of the velocities. *Vis viva* pertains to compression, or, more generally, to the displacement of particles in respect to each other; hence it is sometimes called the penetrating power.

Suppose that the bodies are perfectly elastic; then, without any knowledge of the principle of *vis viva*, we decide that the bodies will have equal velocities after impact, but in opposite directions. By *vis viva* we know as before, that the amount of compression is proportional to the square of the velocities; but on account of the elasticity the *vis viva* (or work) is all restored, so that there is no loss of *vis viva* in perfectly elastic bodies.

Suppose the bodies unequal, non-elastic, and move in opposite directions.

Suppose A weighs 200 lbs. and has a velocity of 2 feet; and B weighs 20 lbs. and has a velocity of 20 feet, required their condition after impact.

With regard to the motion of their masses, they will come to rest, for their momenta are equal, being $200\ 2 \times = 20 \times 20 = 400$ lbs. feet.

But the *vis viva* of A is proportional to . . . $200 \times 2^2 \times 800$
The *vis viva* of B is proportional to . . . $20 \times 20^2 \times 8000$

hence B performs 10 times the labour of A in producing the compression of the two bodies. This at first may appear paradoxical; but two considerations will enable us to make it clear.

1st. It is possible for one body to do all the labour of compressing both bodies; thus, suppose one body moves against another at rest. Now the body at rest has no *vis viva* (or work) stored in it, but the moving body has; hence it performs all the work of compression.

2nd. In the example under consideration; if A can perform 10 times the labour of B; then A would penetrate a clay-bank 10 times as far as B; if the bodies were of equal size: now how can this be if they destroy each other's motion by impact?

We think the difficulty disappears at once by observing that A has 10 times as many particles to bring to rest as B; and hence B must perform 10 times the labour of A to bring them to rest.

It is worthy of notice that if the momentum of two bodies are equal, then their *vis vivas* are inversely proportional to their masses. For we have $M\,V = M'\,V'$;

$$\therefore\ V = \frac{M'\,V'}{M}.$$

Substituting this value V in the expression for the *vis viva*, gives

$$\frac{M\,V^2}{M'\,V'^2} = \frac{M\left(\frac{M'\,V'}{M}\right)^2}{M'\,V'^2} = \frac{M'}{M}$$

It is well known that if the impact of two non-elastic bodies takes place while they are moving in the same direction, their momentum after impact is the same as before, but there is a loss of *vis viva*. Now this loss is expended in compressing, or otherwise disfiguring the bodies.

Other illustrations might be given, but we trust that these will throw some light upon the dark points which may have arisen in the mind of some reader.

In the last example it was said that the *vis viva* of A is proportional to 200×2^2; but the true value is $\frac{200}{g} \times 2 = \frac{200}{32\ 1\text{-}6\text{th.}}\ 2^2$; and similarly for B. Many writers use the weight for the mass too frequently, thereby producing slight confusion. By making such free use of it, the student is at a loss to know when it is necessary to use the mass.—*The Journal of the Franklin Institute.*

CENTRIFUGAL PUMPS.

THE successive improvements which may be traced through the class of water wheels as chief motors in transmitting power, in which the modern turbines are conspicuous, have also suggested a reverse action, by which the wheels and turbines are changed into pumps, of which many different patterns are now and have long been in use, operating as suction and force lift pumps.

The laws of maximum useful effect, which have been very fully and clearly demonstrated for water wheels, as types, apply to their reversed patterns, as to the form and arrangement of the blades, experiment having demonstrated a large increase of the discharge with a change from ordinary radial to properly curved arms, without increase of power. The following abstract of an experiment by Col. Morin, made at the Great London Exhibition, illustrates this point:—

Form.	Revolutions per minute.	Gals. raised per minute.	Height raised.	Useful Effect.
Curved Vanes (Appold's)	792	1164	18 ft. 8 in.	·649
,, ,, ,, ...	788	1236	19 4	·680

With the best form of pump which can be devised, useful effect is controlled by velocity and lift, and the value of this motor is confined to low lifts under excessive speeds. Experiments made on Appold's centrifugal pump show a progressive per centage of work done, under a lift of 5·5 ft., with a 12 in. pump, of 21·2 per cent. for 375 revolutions, 59·1 for 400, 71·9 for 495, an increase to 607 revolutions giving 69·2 per cent. To raise water 67·66 ft. required a speed of 1,322 revolutions; and within their special range of application, 70 per cent. useful effect is all that can be claimed for the best motors of this class.

The laws of form, however, have been much overlooked in those in ordinary use, radial blades being common in practice. For bailing large quantities of water from foundations in excavation, where the supply carries much sand and gravel, for wrecking pumps, and like uses, the facility with which dirt, gravel, grain, &c., are passed through these pumps is a strong point in their favour, while they have no claim to merit on the ground of economy in power.

About ten years ago, some of our scientific journals were agitated by a discussion on the merits of a new theory of centrifugal power, which proposed to regenerate the mechanical world, and overthrow the antiquated notion that a machine could not transmit more power than was imparted to it. It was claimed to be demonstrated at the end of much printing, and was admitted by some of our puzzled savans, that by certain mechanical adjustments an increase of velocity might generate a force of 173,824 foot-pounds from a power of 42,480, and twice the velocity would yield 695,296 foot-pounds for 84,960. But, like all wonderful discoveries of the kind, which seem to lead a comet-ary life, it has vanished in silence from the horizon of mechanical science, to return no more, and to be numbered among the stame and cloud engines, caloric steamers, water gasometers, full steam cylinders, and other celebrities of the passing hour.

From the pertinacity with which some of our engine builders have urged the necessity of an equable motion in pumping, we have been somewhat surprised to see so much neglect shown to the rotary pump, which accomplishes their desideratum in the most perfect manner, and the fact of such neglect must be taken as a strong argument against the reliability and economy of this motor.—*Journal of the Franklin Institute.*

SAFETY VALVES OF STEAM BOILERS.

AT a meeting of the Academy of Sciences of Vienna, M. de Burg gave an account of his experiments on the mode of action of the safety-valves of steam boilers. These results are in contradiction with the theoretical propositions upon which the regulations for the dimensions of these boilers have been based: inasmuch as in reality these valves do not rise to a height equal to one-fourth of their diameter, that is, one or more inches, but only so as to leave a passage for the steam whose diameter does not exceed the fraction of a line. These apparatuses, therefore, cannot fulfil their object, which is to give simultaneous issue to all the steam which a boiler can produce when it has reached a determinate degree of tension, and thus to prevent all danger of explosion. To fulfil this purpose they ought to be at least six times, and in some cases twenty times larger than the rules prescribe.—*L'Institut.*

A mass of copper, nearly pure, has recently been discovered in the Mesnard district, Michigan. It is 40 ft. in length, and about 4 ft. broad, by as many in height. It weighs about 50 tons.

The high celebrity of Mr. Locke was not due to the fact of his making railways. Engineers, of first-rate ability, abounded in England at the time. It was, that he made them within the estimated cost, an achievement which would sooner or later have been attained by the ordinary operations of capital. The Grand Junction Railway was eventually constructed for a sum within the estimate, and at an average cost of less than £15,000 a mile. When that estimate is compared with those of Brunel, the "Michel Angelo" of railway construction, it excites no wonder to find with what eagerness Locke's services were courted both in this country and in France. The heavy works on the Caledonian Line, including the expense of platforms and road-side stations, were completed at less than £16,000 a mile. This economical success was in a great measure owing to the adoption of a bold system of steep gradients—an expedient which Stephenson, it appears, disliked to the last, and which was a prevailing feature in his active rival's designs. Locke hated a tunnel, and with embankments and inclines would encounter any difficulty.—*Saturday Review.*

SOCIETY OF ARTS.

ON BOAT-BUILDING BY MACHINERY.—BY D. PUSELEY.

ON Wednesday, the 3rd inst., Mr. D. Puseley read a paper before the Society on this subject. The following is an abstract of the paper:—

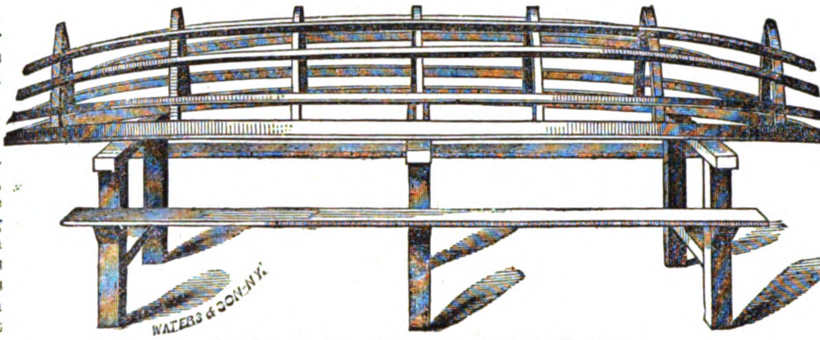

FIG. 1.—ASSEMBLING FORM, WITHOUT FRAMES.

Assembling forms, like boats, are of various shape and sizes. Like the foundation of any other structure, the assembling form in the new system of boat building is the groundwork on which the entire superstructure is raised. While the machines are the mechanical workmen by which all parts of a boat are cut to pattern, or regulated by index to the exact size required, each part fits with the same mechanical accuracy in its allotted space on the assembling form. Every part bears a number or mark that finds a corresponding number or mark on the form. And it is in the great subdivision of labour, by which all parts of a boat are manufactured simultaneously, that the anticipated saving in time and expense will be effected. This sub-division of labour will also apply to the adjustment on the form of the various parts of a boat. And this is the only feature under the new system that requires the exclusive application of manual labour. The final operation must still be performed by those mortal guides without which machinery itself would become a stagnant power.

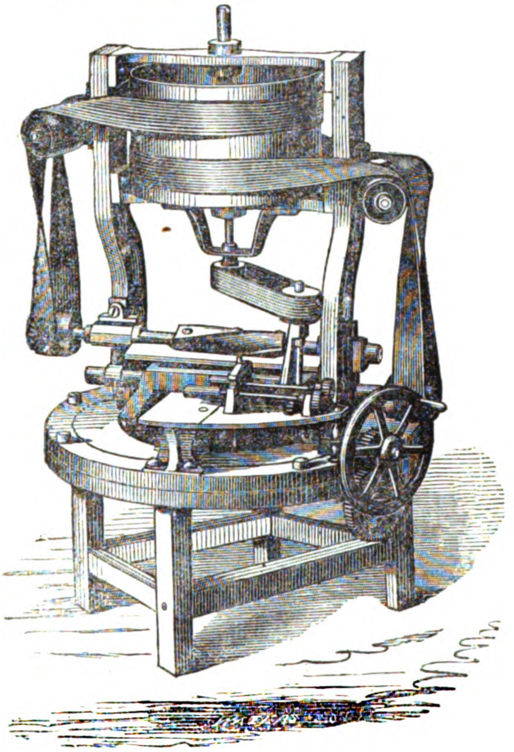

FIG. 2.—DRUNKEN SAW.

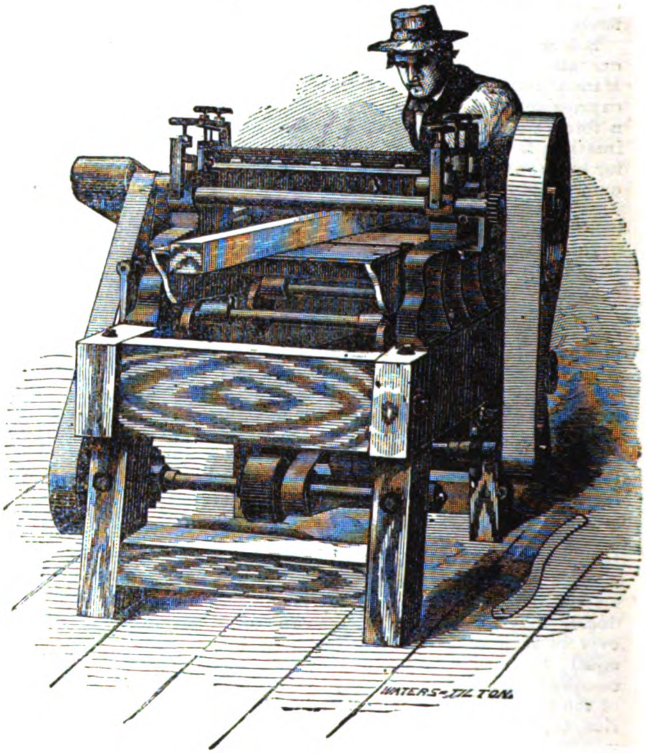

FIG. 3.—PLANING MACHINE.

Before I refer to the machines by which the component parts of a boat are shaped, let me direct your attention for a few moments to the magical performances of a little outsider. Though a grating of trellis-work foot board does not form an integral part of a boat, it is nevertheless a necessary appendage. On the table is the model of a little circular cutter, or—as some call it—a "drunken saw." Yet, even in its unsteady movements, it will accomplish in a few minutes what, by the old system, would occupy one of the most sober of workmen at least half a day. This saw has a lateral as well as a longitudinal set of teeth. By the aid of a small screw lever it is forced from its perpendicular position, according to the width of the cutting that may be required. The irregular or oscillating motion thus produced, when it is revolving rapidly, multiplies the teeth, as it were, till they become a surface cutter or circular plough, that clears everything before it. A counterfeit operation may serve to illustrate the process. Let us suppose that above the surface of the table before which I now stand, this little saw shows its teeth to the depth of the tunnels required in the wood that is to pass over it. Placed on a mechanical guide, the plank is thus conducted over the saw by the workman The result of this operation would be a number of gashes partly through the wood. In another minute the plank has been cut into strips or bars like those on the table. After going through a planing machine, the bars have only to be crossed on the openings prepared for their jointure, and this produces the grating, a specimen of which is now before you.

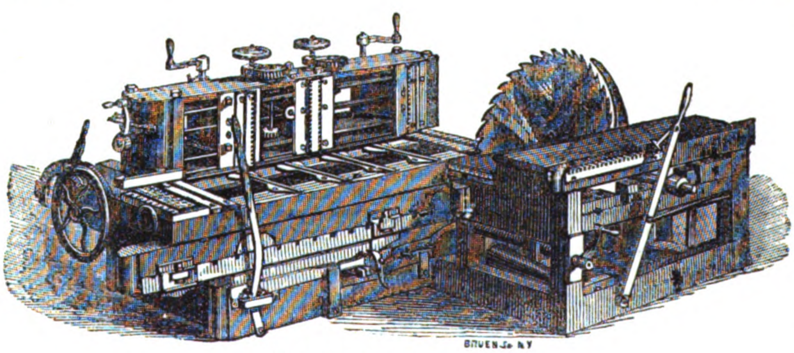

FIG. 4.—COMBINATION SAW.

The *Times* says: — "The whole machinery possesses the same superiority over hand labour that the power-loom has over the by-gone system of knitting. It is the old story of a man working ten hours on wages against a machine that works day and night, and costs nothing but a little oil. Therefore, before long, all boats will be built by steam machinery."

"Here we have the model of what is called a "combination saw" (Fig. 4), a saw for cutting a log of wood into planks. There is nothing very remarkable in the saw itself; but there is a combination of advantages in the mechanical con-

trivances by which the wood is propelled and cut into the various tapering shapes required by the boat-builder.

The next step in the system is to bend these planks into the required form. After they have been prepared for this operation by a steaming process, they are placed under a bending machine, and, by the aid of steam power, they are rounded to the form beneath with as much ease as a boy would bend a small cane across his knee. The woodcut represents the mode of operation, while on the blocks before you we have a couple of planks in their rounded shape. One represents the forward cant, and the other the midships of a boat. The rounded planks, after remaining for some time in a drying room, become as fixed and firm in their new as they were in their original shape. They are then cut into ribs, and, after passing through a planing machine, they constitute the perfect ribs.

As a mechanical curiosity, there is probably not another machine in the entire series to be compared with that which gives to a plank its interior and exterior curve at the same moment. This machine is called a curvilinear cutter or plane. Mr. Thompson was many years before he brought this machine to its present state of perfection, and he worked as only an enthusiastic inventor can work.

On their passage through this machine, the planks required for a boat of any size obtain their interior and exterior curve at one and the same time. The workman or guide has simply to let the index on the machine correspond with the number on each plank; and the cutters or knives, being concave and convex, any degree of concavity or convexity that may be required is at once obtained.

The *Times*, in its notice of the invention, says that "such a machine, up to the present time, has been deemed a mechanical impossibility, and that the search for its discovery has been as futile as that for the philosopher's stone." So says the *Times*. Yet, in the rapid advances now made by scientific men, the *Times* itself can hardly keep pace with some of the "great guns" of the day. Here is a model of the machine, together with a specimen of manufacture.

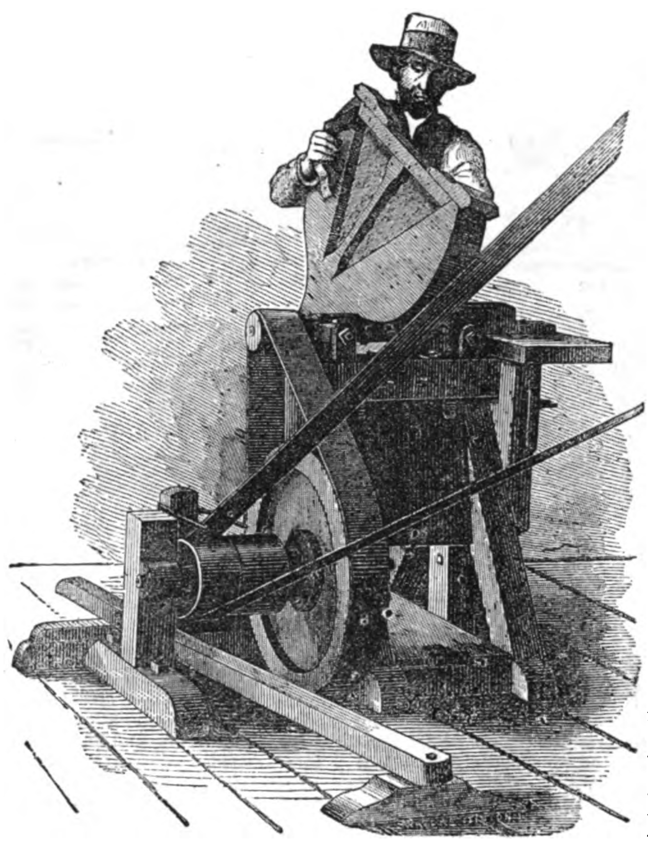

FIG. 5.—STERN-POST MACHINE.

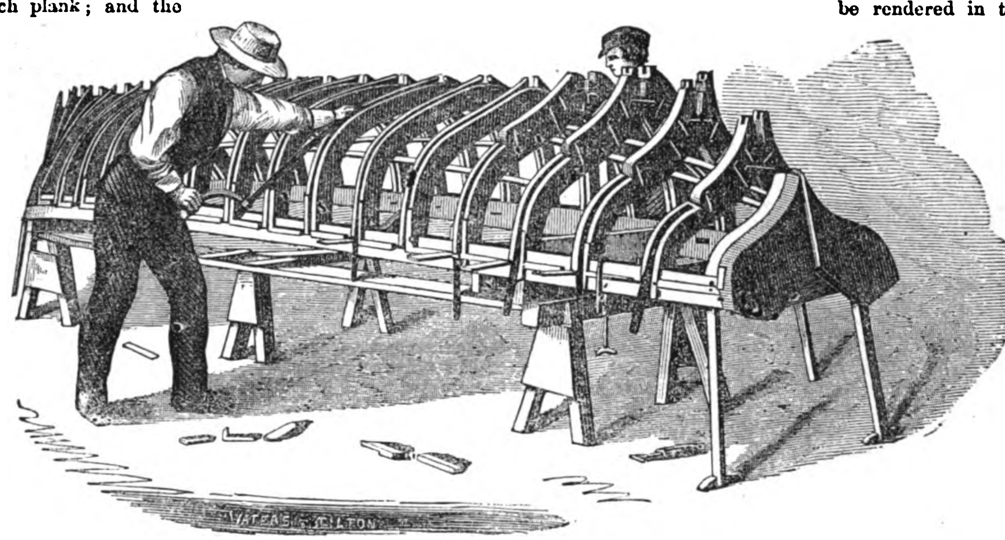

FIG. 6.—ASSEMBLING FORM, WITH FRAMES ON.

To enable those who read this paper to understand it—as well as those who hear it read—it may be necessary not only to offer a few more explanations concerning the machines that are used in the manufacture of the various parts of a boat, but also to furnis one or two more illustrations in order to show the system, after every part has been shaped, by such machines, and is ready for its final adjustment. With regard to the machines, it is impossible to convey a correct idea to others, or for others to form a correct idea of their mechanical peculiarities, unless by a critical and personal examination. While there are nearly twenty machines used in the manufacture of the various parts of a boat (all in operation at the same time), and while the functions of each machine are of a distinctive character, it would take a good-sized octavo volume to enter fully into the particular properties of the entire series. To be fully comprehended, the system must not only be studied in its entirety, but witnessed in operation.

In addition to the cutters previously referred to, here is an elliptic knife, or diagonal cutter. Fig. 5.)

All that can be said (to be understood) is, that the machine consists of a rotating knife, with an adjusting guide, enabling a clean cut to be made on the edge of any plank or block of wood, from a square to an angle or bevel of 45 deg., according to the inclination given. The illustration represents a workman in the act of giving the required bevel to a stern-board. This machine, at the lowest computation, will perform the work of a dozen men working under the old system.

As I have previously stated, every boat built by the new process is built on an assembling form. In the naval and mercantile marine there are (together) about thirty standard sizes, shapes, or classes of boats, and forms to that number will always be kept on hand, while for any person who might require a boat or a number of boats differing from either of these shapes, an alteration, addition, or, if necessary, a new form can be made.

Fig. 6 shows the process of putting the frames on the assembling form, when such forms are ready for adjustment.

And Fig. 7 illustrates the mode of planking, which is the final operation, previously to the boat being hoisted from the form on which it has been built.

There is one point to which I have not before referred. Next in importance to the power of being able to supply the extended demand that must arise in the boat-building trade, through the increased facilities for supply, is that system or process in Mr. Thompson's invention, which enables the inventor to furnish with each and every boat a duplicate part, or duplicate parts thereof. By such duplicate parts, any damage a boat may sustain can be at once repaired, without the delay, trouble, and expense either of of sending it to a boat-builder, or having it patched up by incompetent hands and insecure means. Further than this—accidents to the boat or boats of a ship often occur at times and places in which boat-builders or carpenters may not be within reach; often, too, when, if such aid could be immediately procured, the service required could not be rendered in the brief space that would make it of any use. This want will in future be supplied, and the countless, and sometimes fatal, inconveniences that have hitherto arisen, will be entirely obviated in Mr. Thompson's system, by which the duplicate parts of a boat can be easily fixed.

DISCUSSION.

Mr. Thompson (having been introduced to the notice of the meeting by Mr. Puseley) begged, on behalf of himself and those associated with him, to return his thanks to that gentleman for the way in which he had brought forward the subject. It was, he said, one thing to invent, and another thing to be able to properly describe the invention; he must, therefore, leave it to speak for itself. It was impossible to give any detailed explanation of the various machines, the models of which were before them, further than had been done by Mr. Puseley, and it was necessary to see them in operation properly to understand them.

Mr. Green having pointed out the description of work which the several machines were designed to execute,

A Member inquired how many separate machines were required to prepare all the materials for a boat.

Mr. Thomas replied, seventeen. It was further explained that the machinery now erected at the company's works at East Greenwich was adapted for any boat, from the smallest size up

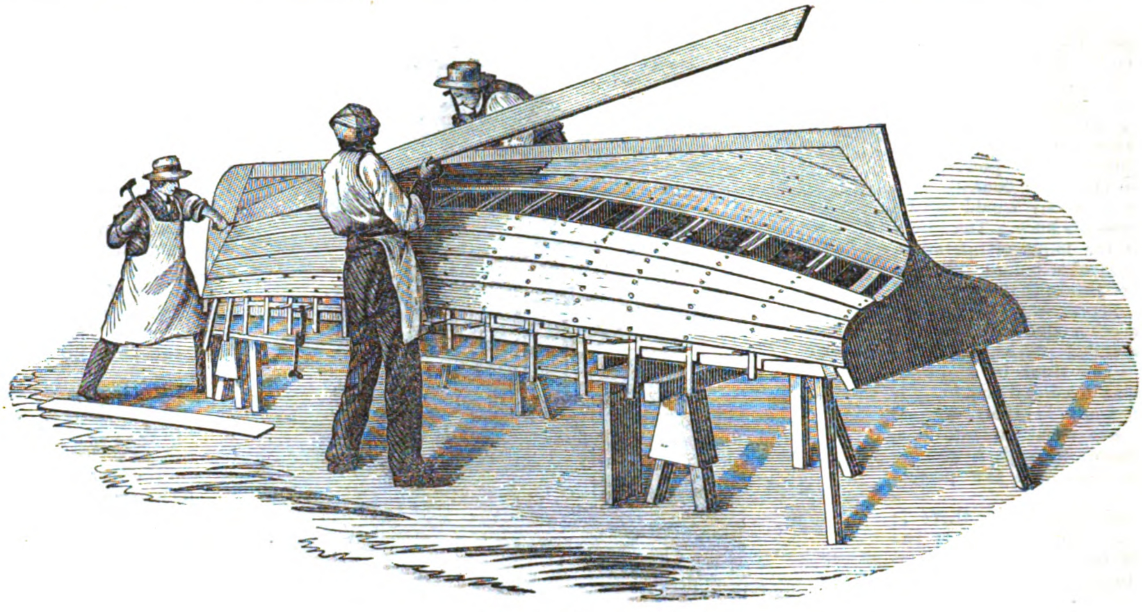

FIG. 7.—PLANKING.

to 32 or 40 ft. in length. The steam-power employed consisted of two engines of 40-horse power each. The only operation left to be performed by manual labour was the putting of the various parts of the boat together on the "assembling form," after they had been prepared by the machinery.

Mr. Peter Graham said, having seen the machinery in operation, he could entertain no doubt of its efficiency as a substitute for manual labour in the preparation of all the parts required for the construction of a boat. The saving effected was in the labour, because the material was the same whether prepared by manual labour or by machinery. Mr. Turner, master shipwright at the Royal Dockyard, Woolwich, had expressed his opinion that the saving in labour effected by this machinery might be represented by the ratio of seven to thirty-two, or, in other words, that the cost by machinery was less than one-fourth that by manuel labour. That, he thought, was a fact of great interest to the commercial community, who might expect to be supplied with boats at a much cheaper rate than heretofore. At the same time, the company by whom the patent rights of the inventor had been secured in this country, expected to realize a fair return for the capital invested. In reply to an inquiry as to how long it took to put a boat together after the material had been prepared, Mr. Graham said that depended upon the number of men employed on the work; but he believed it could be done in from five to ten hours, according to the number of hands employed and the size of the boat. The great advantage consisted in the facility afforded by this machinery of making an unlimited number of *fac-similes* of each particular part of a boat, so that duplicates of parts likely to be injured might be supplied and fitted by unskilled hands in any part of the world. That was important in the case of ships at foreign stations, where there was a difficulty in getting boats repaired. He quite agreed with Mr. Thompson, that in order properly to appreciate this machinery it should be seen in operation; and he might state that as soon as the works were started, which would be in the course of a very few weeks, those who were interested in the subject would be admitted, under proper regulations, to witness the operations.

Mr. Brooks wished to be informed whether Mr. Thompson claimed to be the inventor of that portion of the machinery which was termed the "drunken saw?" Having seen these models in the International Exhibition, he admired the principle upon which they were constructed, but he pointed out to the person in attendance as Mr. Thomson's representative, that there was no originality whatever in the saw described, inasmuch as the drunken saw had been in operation in his own works for the last nine years, and had produced work of greater excellence than the specimens he saw at the Exhibition. Nine years ago one of his workmen invented this arrangement of the saw, and it was a curious coincidence that the term "drunken saw" should then have been applied to it, and repeated in the present instance. He should be glad to be informed whether the idea as to the originality of the invention came across the mind of Mr. Thompson when he took out his patent in 1860. It was not his (Mr. Brooks's) intention to discuss the details of these seventeen various machines. Many of them showed great skill in their design, and were doubtless original, but the question for discussion was not the quality of the workmanship, but who was the rightful inventor of some of the machines of which there were models before them? With regard to a portion of them, at least, he thought they could not be claimed as of American origin; if they were, they must have existed in the brain of Mr. Thompson more than ten years ago. He should be happy to show Mr. Thompson, or any other gentleman, the "drunken saw" which he had had at work for the last nine years, and at the same time should feel great pleasure in availing himself of the invitation that had been given to inspect the works of the National Boat-building Company.

Mr. Thompson said, with regard to the drunken saw, he had laid no claim to its invention. It had been in use in the United States of America for at least forty years. All he claimed was the adaptation of that implement to its present purposes, and the peculiar arrangement for producing the oscillating motion given to the saw. The system of machinery in its entirety was what he laid claim to, and its adaptation to purposes to which it had never been previously applied.

Mr. Puseley said it was distinctly stated in the paper, that while some portions of the machinery were originated by Mr. Thompson, he had also adapted previous inventions to his purpose. He had never claimed to be the inventor of the drunken saw. As a whole, he had adapted this machinery for the purpose of preparing the material for boats in one-fourth of the time it could be accomplished by manual labour.

Mr. Turner (of Woolwich Dockyard) said, about two years ago he inspected Mr. Thompson's machinery, and was much delighted with it. By its means, every portion of the material of a boat was taken in hand simultaneusly, and prepared with a mathematical precision which it was impossible to effect by manual labour. In a boat built in this manner, every part of the structure was brought in contact and fitted accurately. He was altogether delighted with the invention of Mr. Thompson, and wished him every success.

Mr. Thompson begged to ask Mr. Turner whether he had ever seen the same ends accomplished by similar means?

Mr. Turner replied that he had not.

In reply to an inqniry by Mr. Charles Clifford, as to the variety of form and size of boats which could be manufactured by the machinery set up by the company,

Mr. Peter Graham said they had at present twenty-six assembling forms, which were adapted to as many descriptions and sizes of boats. Any variation in the particular form of a boat would, of course, require a separate assembling form; and as these forms were somewhat expensive, it would not answer to make a form merely for half-a-dozen boats of a particular model. The forms already prepared, and the machinery set up, were adapted for boats up to thirty-two and perhaps forty feet in length, and fifty tons burden. If a demand arose for a large number of boats of a particular size and model, the assembling form would be prepared; the machinery could be adjusted to every variety of size. The system was equally adapted for cutters of extremely fine lines and boats of broad beam.

The Secretary said the machinery would fashion the materials for any form of boat that was demanded; but, in order to put it together, an assembling form must be prepared of the model required. If a form was made merely for one or two boats, of course these could not be built relatively so cheaply as a larger number of the same form; but the machinery was adapted for any lines that might be required.

Mr. Peter Graham added, that the cost of the materials would be the same, whether prepared by manual labour or by machinery; but the labour in the preparation was reduced by machinery to about one-fifth that of hand labour.

Mr. Turner remarked that the great point of the invention was the rapidity of production. He believed Mr. Thompson could build a boat complete in five hours.

Sir Thomas Phillips said he thought they were discussing, with too great minuteness, the details of the invention. All that was intended to be done was to submit to the society a series of machines whereby a boat might be built in a very short space of time, with a great economy of labour. To Mr. Thompson certainly belonged the merit of having produced a great many ingenious machines, which he had applied to the effecting of a particular object, and in that he

apprehended the inventor had entirely succeeded. They had been assured, by a gentleman holding an important position in the public service, that he was satisfied that, by these means, a boat could be built in an exceedingly short space of time, which was a most important object to be secured. So far, then, there was neither doubt nor difficulty. Whether or not the system would be productive of any great amount of commercial gain, must depend upon its practical adaptation to the wants of the community. There could be no doubt if, instead of varying indefinitely the type of the boats, they could build boats of a certain capacity of tonnage, upon a particular plan, whereby they might produce a large number of the same type, the economy which was promised by this plan would be secured; but it was obvious that it wovld not answer the purpose of these gentlemen to take an order for a single boat of an exceptional form, inasmuch as the commercial results must depend upon the production of a large number of a given type. With regard to the question whether Mr. Thompson was the inventor of a particular machine or not, that was not a matter of any great interest to this meeting. The question was this — had Mr. Thompson adapted machinery — no matter by whom invented—and rendered it applicable to a new object, which hae never before been accomplished by machinery? If he had done so they would regard him as a public benefactor; the invention was in itself a highly creditable thing to Mr. Thompson, who had no doubt devoted a considerable portion of his life to the production of this system, and if he succeeded in producing great commercial advantages, the public at large would have the benefit of them; but if he did not succeed, he (Mr. Phillips) was sure they would accord to him that sympathy to which all men who pioneered for the good of society were entitled.

The Chairman said that, after the numerous explanations that had been given, very little was left for him to say on the subject, bnt there were one or two points which occurred to him, having witnessed the whole of the operations, and being himself a practical man in these matters. All the materials for a boat might be cut out and prepared by this machinery for putting together. It then required skilled workmen to put the parts together. One point requiring consideration was, that the planking, being cut by machinery, they might fall into the error of its fitting too well, because it was neccessary to caulk it, and if the boat were not built for caulking she would tear herself to pieces. The grating, of which they had seen a specimen, had been produced in a somewhat similar manner for nearly fif.y years past, but not prepared precisely in the same way. It was produced be a series of teeth, on the periphery of a wheel, so placed as to come into action in succession, an arrangement similar to what was used in Woolwich Arsenal for planing gun carriages in 1810. It had been seen that if a boat was required of a different form—whether leaner or broader—it was very easy to fit battens on the outside of the assembling form, so as to adapt it to the required shape. There was a great advantage attending the planking prepared by these means, namely, the cutting of the planks to fit the curves of the boat, without straining them to bring them into position. In point of fact, he believed his friend, Mr. Turner, would say they were in the habit of putting too much stress on a boat, instead of adapting the planking to fit without straining. The rabbeting of the keel, stem and stern, by this process, was very complete, and no man could arrive by hand at the precision which this machinery produced. With regard to the question of duplicate parts, he was not quite.disposed to fall into the views expressed. If they had duplicate parts to take with them they must have literally duplicate boats, but the real advantage was, that duplicates could be kept at foreign stations, where a captain of a ship might take the duplicates and either repair or build a new boat, or three disabled boats might perhaps build two complete ones. The parts prepared by this machinery might be likened to the component parts of a watch, which were made by machinery and sold to a manufacturer for a small sum, and he eventually finished them up to form a complete watch, or even a chronometer. So in this case, with a slight finishing, these machine-prepared parts might produce a perfect boat. With regard to the question of the drunken saw not having been the invention of Mr. Thompson, that was not now before them. Mr. Thompson did not claim it, but if he had done so, it was a question of law, and the man who claimed the patent must make good his right if he could. Mr. Thompson had gone through the fire nobly, and he wished him every success; he was sure this Society would be very glad to thank him and Mr. Puseley for having brought this very interesting subject before them.

Thanks were then voted to Mr. Thompson and Mr. Puseley.

EXPERIMENTAL FIRING OF THE BIG GUN UPON THE "PASSAIC."

According to a New York paper, a few weeks since, the gunboat, "Passaic"—which has already been described in our columns—made her first trial trip, to test her machinery, and also the firing of the huge 15-in. gun in her turret. The experiment with the gun was of great consequence, as it is the largest piece of ordnance ever tried on shipboard. As the port-hole for the gun is only 17 in. in diameter, and the face of the gun is nearly 29 in. in diameter, the shot has to be fired through the hole, because the muzzle cannot enter it. The recoil of the first shot was so great that a large quantity of the smoke from the discharged powder remained inside of the turret. To remedy this evil, a muzzle-box was constructed for the turret, and a second trial trip of the "Passaic" took place on Saturday, the 15th ult., but with results little more favourable than on the previous occasion. The vessel proceeded some distance up the Hudson river, and three shots were fired toward the Palisades. The gun was first charged with 20 lb. of powder, and a shell of 330 lb. weight. Two other shots were then fired, with similar shells, and 35 lb. of powder, when the muzzle-box burst, and the vessel returned; but, fortunately, no lives were lost. New experiments are now in preparation.

The mechanism for operating this gun was invented by Captain Ericsson, and has been highly commended; no offensive jarring from the recoil of the discharge was experienced inside of the turret. A short time since we pointed out the ignorance of the *Times* in descanting upon the working of navy guns. The "Thunderer" stated that it was impossible to operate guns over five tons weight on ship-board. In the case of the "Passaic" its big Dahlgren gun, weighing nearly 19 tons, was handled without difficulty by half a dozen men. The largest guns hitherto used in the American navy have been 11-inch Dahlgrens; the largest smooth-bores in the British navy are only 8-inch, or 68 pounders. The employment of such large guns as the one placed in the "Passaic" is a new and important step in naval warfare. As the diameter of the bore of a gun is increased, the weight of the spherical shot increases according to the cube. Thus, while a round shot, for an 11-inch gun, contains 696·91 cubic inches, the round shot of a 15-inch gun contains no less than 1767·15 cubic inches; hence the necessity for making guns proportionately so much heavier as the bore is increased. The speed of the "Passaic," on her second trip, also exceeded that of the first trip by more than one knot per hour.

Proceedings of Societies.

THE LONDON ASSOCIATION OF FOREMEN ENGINEERS.

On the night of Saturday, the 5th instant, the ordinary monthly meeting of the above-named society took place at 35, St. Swithin's-lane, City, Mr. Joseph Newton occupying the chair. After the transaction of some routine business, and the election of several members, Mr. J. Dickinson Brunton proceeded to read a paper on "Peat." Mr. Brunton commenced his remarks on this highly-interesting subject by referring to the enormous deposits of peat which exist in various parts of the United Kingdom, and to the comparatively fruitless efforts which had hitherto been made to turn that material to useful and profitable account. He stated that the peat beds of Great Britain and Ireland covered an area of not less than six millions of acres, and assuming the average depth of these beds to be 12 ft., and this was a low estimate, each acre would yield 3,600 tons of dried peat. The aggregate quantity of peat in these islands would, therefore, yield twenty-one thousand millions of tons, and this would give a supply of twenty-one millions of tons per annum for a thousand years! The questions next arose as to whether it was possible to convert this store of raw material into fuel, and to make it, not only serviceable, but a profitable article of commerce. From a series of experiments which had recently been made under his own observation, Mr. Brunton believed that peat might be so treated as to make it a formidable rival to Coal and Coke, both as regarded efficiency and cost.

In proof of this the writer of the paper pointed to a number of specimens of peat in various stages of conversion, which were placed on the table before him, and to some samples of Iron which had been smelted by the use of peat charcoal alone. These specimens and samples were passed round to the numerous members who listened to the paper, and so far as it was possible to judge from such evidence, they all seemed willing to allow that a considerable amount of success had been attained by Mr. Brunton and his co-experimenters. The peat had been converted into dense hard masses, evidently capable of withstanding the blast of an iron furnace; whilst the iron, which had been produced from iron-stone lying beneath a peat bog near Sligo, in Ireland, presented all the appearance of the finest importations from Sweden. Mr. Brunton next explained to his audience the mode by which the peat fuel had been produced in the state in which it was now exhibited. A simply-constructed machine, of which a diagram was shown, was the principal agent in the work. When the peat was dug from the bog it was thrown into a hopper at the top of the machine, and immediately beneath the hopper was a strainer formed of perforated metal. Within the strainer was an iron archimedian screw running upon vertical axes. At the bottom of the strainer a small opening was left, and through this, very coarse, undecomposed roots and fibres, which would not pass through the perforations of the strainer, fell. By turning the screw the small fibres of the peat were cut up by forced contact with the sharp edges of the perforated metal, and becoming assimilated with the decomposed parts of the peat, passed through the perforations.

A strainer, of 2 ft. in diameter, with perforations of an eighth of an inch diameter, and 15 to the square inch, contains about 12,000 holes, equal to an aggregate aperture of 1 square foot, and this was made to discharge about 8 tons of peat per hour. When in operation, the decomposed peat exuded through every hole in the strainer, and, dropping in vermicular form, upon an endless band, was conveyed by it to another contrivance, closely resembling a brick-making machine. In this the peat was moulded into form. As the strainer was enclosed in a heated chamber, with an opening for the escape of steam, the moisture was driven rapidly off from the worm-like strings, as they fell upon the band, and the subsequent solidifying process was thus facilitated. A very short time sufficed for drying the resulting blocks of fuel. No kind of compression was exercised, and very little power was required either in disintegrating the fibres, or shaping the blocks.

Such in reality were the sole means employed in the preparation of the material to which had been given the name of "Condensed Peat." Several certificates from eminent practical engineers, who had tested it in the furnaces of marine, locomotive, and stationary engines were read, and these were all favourable in the highest degree.

At the conclusion of Mr. Brunton's extremely lucid paper, the Chairman invited a discussion thereon, and in this Mr. Oubridge, of Messrs. Simpson's, Pimlico; Mr. Shotton, of Messrs. Humphrey and Tennant's, Deptford; Mr. Ives, of Messrs. Grissell's; Mr. Moore, Mr. Zohrab, Mr. Buckle, of the Mint, and other gentlemen took part. Many questions were put as to the cost of the manufacture of the peat, and the price at which the Sligo iron could be supplied. These were all answered satisfactorily, and so far as experiments have gone, under the hands of Mr. Brunton and his friends, there

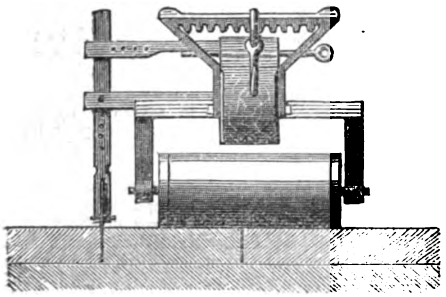
does seem reason to hope that peat fuel may yet play a very important part in the further development of the mechanical arts of the country.

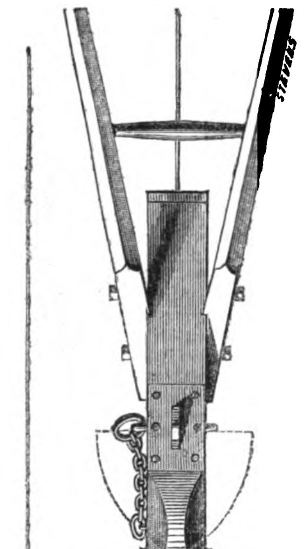
In proposing a vote of thanks to the reader of the paper, Mr. Newton said that he considered the society much indebted to that gentleman for the pains he had taken in preparing it, and that he had thrown a very clear light upon a subject which had been somewhat neglected. It is needless to say that the vote was unanimously agreed to; and at half-past ten, the meeting came to an end.

We have still to regret the non-attendance of Employers at the sittings of this society. They may rest assured that themselves, and not the members of the Association, are losers by their absence; and the great success achieved by the unaided efforts of the Foremen Engineers is the best proof that their course of proceeding is a right one. Such a meeting as that of Saturday last would scarcely have discredited the Institution of Civil Engineers, or the Society of Arts.

COOKE'S TURF CUTTER.

This Invention, just patented by Mr. B. Cooke, of Devonport, relates to a novel construction of implement for cutting turf, the object being to simplify the construction and increase the efficiency

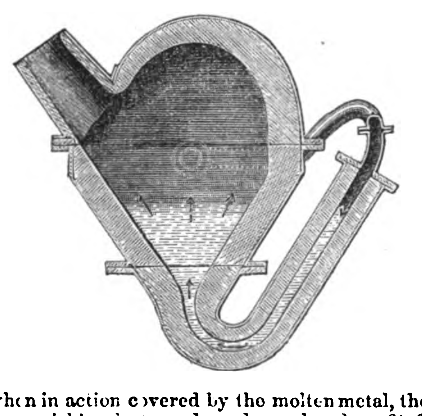




of such implements. In construction, the implement is somewhat like a subsoil plough, as represented in the accompanying engravings. The forward end of the beam is fitted with a brake, which is adjustable vertically by means of a cross pin. On the opposite sides of the beam are wrought-iron brackets, which form the bearings for a transverse roller. This roller precedes the coulter, by which the turf is cut and is intended to level the inequalities in the turf, and remove the hoof prints of the horse. It is made of cast-iron, and hooped with bands of wrought-iron. In rear of this roller is a coulter, the stem of which passes through a socket made for it in the middle of the beam, and carries at its lower end a horizontal share or pointed flat blade, the breadth of which is equal to the width of turf required to be cut. The coluter is held in position by means of metal keys or wedges, and its height is adjusted (to suit the depth of cut required) by a cross pin that passes through the coulter stem, a series of holes being formed therein to receive the pin. The cas-iron roller is fitted with a scraper for keeping its periphery clean. Near one end of the roller runs a guide wheel, in the track left by the last vertical cut of the coulter. This wheel is carried by a stem, which is itself supported by slotted brackets, and thus the wheel admits of being adjusted, both vertically to suit the required depth of cut, and literally to adapt to various breadths of turf.

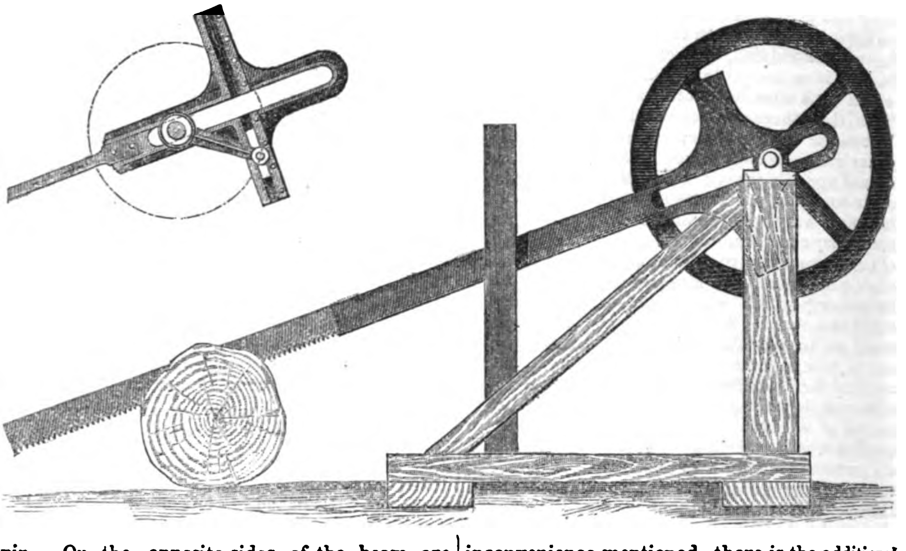
WILSON'S IMPROVED CRUCIBLE FOR THE MANUFACTURE OF IRON AND STEEL.

In the manufacture of malleable iron and steel by the well-known process of forcing atmospheric air beneath the surface of the molten metal, it has been found that by reason of the tuyeres or air pipes being situated at the bottom of the converting vessel, and being consequently always



when in action covered by the molten metal, they are quickly destroyed, and rendered unfit for service. Their renewal is a serious inconvenience, and occasions a serious loss of time, as the converting vessel at each renewal must be allowed to cool down before a fresh tuyere or set of tuyeres can be introduced. In addition to the inconvenience mentioned, there is the additional inconvenience in the old arrangement that the molten metal is apt to flow into the tuyere the moment the upward blast ceases, and thus they become plugged up. The accompanying engraving shows in cross section a crucible just patented by Mr. E. B. Wilson, of Parliament-street. The vessel or crucible is made of wrought iron lined with fire-brick, or other suitable refractory material, and suspended on axes or trunnions for tipping. The tuyere or blast pipe is placed above the molten metal in the manner shown. The arrows show the direction of the air through the metal.

CHILD'S MECHANICAL MOTION.



CHILD'S APPARATUS FOR CHANGING A ROTARY INTO A RECIPROCATING MOTION.

Many of our readers will, no doubt, remember a strange looking apparatus near the south-eastern door and in the American show of the International Exhibition. It was applied to a cross-cut saw for cutting down trees or sawing logs into lengths. This application is the one we now illustrate. The inventor, however, proposes it for any purpose where a change from a rotatory into a reciprocating motion is required.

The change of motion is effected by means of a crank-shaft working in a slot formed in a long arm to which the saw is secured. The end of the crank is fitted with a block which runs in a groove cut in arms or projections formed at right angles to the long arm.

The Post-office money order system has been introduced into Turkey, and postage stamps are about to follow.

A member of the American Institute recently had occasion to examine some very old books, and was impressed with the difference between the paper of which they were made, and the paper that is manufactured at the present day. In tearing that old paper a very rough edge was formed by the long fibres of the material; but if a piece of modern paper is torn, the edge formed is very smooth, showing a very short fibre. This is owing to the use of the material so many times. It is collected and worked over and over until the fibres are broken into short pieces. These broken fibres will not answer for filtering paper, for paper made of them, if placed in water, would be converted into pulp. The filtering paper used in chemical analyses is all made in Sweden. It is retailed in this market at 12 cents. a sheet. Photographic paper was, at one time, all made in England; then in France; but now Saxony makes the best, and principally supplies the markets of the world. It must be made of perfectly uniform materials.

According to M. Michel Chevalier's late paper in the *Revue des deux Mondes*, the Pacha of Egypt has ordered 20,000 uniforms for his soldiers, all the buttons on which are to be of massive silver. We do not know where the order has been executed, but as the buttons are of real silver, we suppose that Germany was not the place.

FIELDEN'S IMPROVED SIGNAL LAMPS.

THE accompanying engravings illustrate a very ingenious invention, recently patented by Mr. A. H. Fielden, of Castle-street, Holborn. It consists in using glass rods or tubes, either in a bent or curved form, for the purpose of obtaining any desired device, or straight, for ordinary lighting purposes. The tubes may be filled with liquids of any colour or combination of colours, and are especially suitable for signalling on railways or in lighthouses. Fig. 1 shows a lighthouse with a lamp of the above description fitted to it. Fig. 2 shows the lamp in use on a railway semaphore. And at Fig. 3 and 4 it is fitted as show lamps, for the outside of buildings and other places. The inventor does not confine himself to filling the tubes with liquid, as they may be of stained glass if desired.

WELLS'S CLAMP FOR JOINERS.

A PATENT has just been obtained by Mr. W. H. F. Wells, of Woolwich, for an improved clamp for the use of joiners and others engaged in working wood. The accompanying engravings illustrate the clamp in two of its simplest forms. It consists of a notched or plain bar of metal of any desired length, according to the purpose for which the clamp is to be applied. When one arm only is used, the end of the bar is turned up to form an abutment or pressing surface, against which one side of the material to be clamped is placed. The sliding arm is self-fixing by its peculiar form, and, when placed in the proper position upon the bar, forms the other abutment. An adjusting screw, fitted either in the head of the bar or in the end of the sliding arm, or in both, completes the clamp. In place of turning one end of the bar up, a plain bar notched in opposite directions, and two sliding arms may be added. The sliding arms are formed wiih a hole or slot at one end, through which the bar can be passed. The arms can thus be moved along the bar so any required position. When a plain surfaced bar is used, these arms are self fixing by the resistance offered by the material to compression when the clamping screw is turned, and, for light work, a plain bar, with an accurately fitting slot in the sliding arm, will be found sufficient. The arm and bar socket may be in one solid piece of metal, or in two parts fitted together with rabits or screw dowels; when made in two halves, or parts, the screw dowels at the back of the bar, when required, are formed with heads projecting a little at the sides, so that they afford the means of slightly diminishing the size of the socket, and thus tighten it upon the bar; an opening of about 1-32 of an inch, being (cut when solid) left when formed in parts for this purpose. For heavy work the arm is made solid, and is self-fixing at and by the notches on the bar. In this case the slot is formed rather larger than the bar, and in an oblique direction through the arm which stands at right angles to the bar when fixed. The arm can thus be inclined a little towarde the head of the bar, or when two arms are used towards each other. In this inclined position the arm or arms can be moved along the bar freely over the notches, and when brought to the required position, and turned square with or at right angles to the bar, the acute angle of the metal side of the slot passes into one of the notches on the bar, and the arm, while it remains at right angles to the bar, is thus rendered self-fixing; a screw or wedge passing into one end of the slot may be added, if necessary.

DIAMONDS USED FOR BORING INTO HARD ROCK. —An instrument for this purpose is now being employed in France, made out of a tube furnished with a circular cutter of rough diamonds. It is caused to revolve, and as it enters into the stone the cutter scoops out a cylinder, which is afterwards easily taken out of the tube. Holes in hard granite for blasting purposes, ·47 millimetres in diameter, and from 1·10 metres to 1·20 metres deep, are thereby bored in one hour. This would require two days work in the ordinary way. The diamonds, when examined through a magnifying glass, do not seem at all injured.—*Cosmos.*

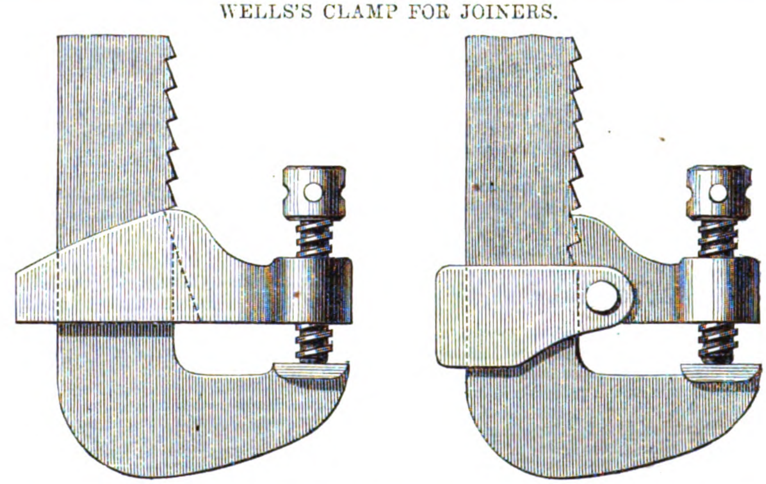
WELLS'S CLAMP FOR JOINERS.



Legal Intelligence.

THRASHING MACHINES.—Prolongation.— Goucher's Patent, Nov. 15, 1862.—This was an application to the Judicial Committee of the Privy Council, before the Right Honourable Lord Chelmsford, and Lords Justices Knight Bruce and Turner, for the prolongation of letters patent, dated 25th Nov., 1848, to Mr. John Goucher, for an invention of "A machine for thrashing corn and other grain."

Mr. Goucher was examined at great length in support of his petition for a prolongation of the original term of his patent, and stated his invention to consist of an improved form of beater for thrashing machines; the ordinary beater consists of several longitudinal bars, attached to arms or spokes, or to the periphery of wheels affixed to a central shaft or axis with which the beater revolves. Mr. Goucher alleged that this form of beater, on the introduction of steam thrashing machines, was found to crush and bruise the corn; his invention, intended to obviate this objection, consists in making these beaters or bars with grooves or channels on their surface, by which both the straw and grain are preserved from being broken.

The specification describes two forms of beater, one of which consists in forming the bars with grooves or channels on their beating surface: the other plan simply consists in winding iron round the edges of plain bars.

It appeared from the evidence that Mr. Goucher was not able to introduce the new beaters for a considerable time after the date of the patent, and one reason for this was stated to be the great difficulty he met with in procuring bars of such a nature as to stand the wear they are subject to. The patentee had granted a mortgage of his patent to his solicitor, and a peculiar feature in the case consisted in the fact that the mortgagee was not only no party to the application for the extension, but no accounts of his receipts and payments was produced, although they are admitted to have been considerable.

The only question left for consideration was the amount of royalties received by the patentee. But he alleged that (principally in consequence of his experiments upon iron intended for his beaters) he had lost about £2,000, by the patent.

Lord Justice Knight Bruce, stated that their Lordships were of opinion that the invention was one of considerabe merit, and although not satisfied with the accounts, they should recommend her Majesty to grant a prolongation of the patent for three years.

The accounts, including the accounts of the mortgagee, to be laid before the Attorney General, who would determine whether they had been fairly made, and what were the fair results of profit and loss by the invention. Their lordships had further agreed that if the Attorney-General should be of opinion the invention had produced a clear profit of £2,000, that no prolongation should be granted, and also that in case of a new term the mortgagee and inspector should remain in the same position, with respect to it as to the present one.

Mr. Grove, Q.C., instructed by Messrs. Pritchard and Collette, for the petitioner; and Mr. Webster, instructed by Messrs. Tweed and Hughes, of Lincoln, and Mr. J. Henry Johnson, of Lincoln's-inn-fields, appeared to oppose, on behalf of Messrs. Clayton and Shuttleworth, of Lincoln, but the opposers were not allowed to be heard, in consequence of their notice of objections being lodged five days after the time limited by the advertisements for the entry of caveats.

The Attorney-General was present in behalf of the Crown.

At a private hearing before the Attorney-General, the extension to three years was confirmed.

Court of Queen's Bench, Guildhall, December 10.—Simpson and others *v.* Wilson and another.—Sir F. Kelly, Mr. Grove, Q.C., Mr. Bovill, Q.C., Mr. Drewry (of the Chancery bar), and Mr. J. A. Russell, were for the plaintiffs; Mr. Hindmarch, Q.C., and Mr. John C. F. S. Day, were for the defendants.

This was an action by the assignees of a patent, sealed on the 13th of July, 1860, and granted to Mr. Henry Medlock, analytical chemist, of Great Marlborough-street, for improvements in the preparation of red and purple dyes. The plaintiffs, Messrs. Simpson, Maule, and Nicholson, are the well-known manufacturing chemists, carrying on their business at the Atlas Works, Newington-butts, and they sued Messrs. Wilson and Co., also manufacturing chemists, in Jubilee-street, Mile-end, for an infringement of the patent above mentioned, which has acquired considerable value by means of its producing the fashionable Magenta red and purple colours. It appears that Mr. Edward Chambers Nicholson, one of the plaintiffs, discovered, after many experiments, that these beautiful dyes could be produced by a combination of aniline (a substance extracted from coal tar) and arsenic acid, but he also found, on provisionally registering his invention, that the same discovery had been made by Mr. Medlock, and patented some short time previously. Under those circumstances, he and his partners purchased Medlock's patent for £2,000, and the claim under that patent was for the manufacture or preparation of red and purple dyes by treating aniline with arsensic acid, as described in the specification, which was in these terms:—

"I mix aniline with dry arsenic acid, and allow the mixture to stand for some time, or I accelerate the operation by heating it to or near to its boiling point, until it assumes a rich purple colour, and I then mix it with boiling water, and allow the mixture to cool. When cold, it is filtered or decanted. The aqueous solution which passes through the filter contains a red colouring matter or dye, while a tarry substance remains in the filter. This tarry substance, dissolved in alcohol, methylated spirit, or other suitable spirit, furnishes a purple dye. These solutions of colouring matter may be used at once in the process of dyeing, concentrated or diluted, according to the tints required. The mixture of aniline and arsenic acid after being heated may be allowed to cool, and then forms a paste, which may be preserved. When required for use it is mixed with boiling water, and treated as above described. I have found that the proportion of two parts by weight of aniline to one part by weight of arsenic acid yields a good result; but I do not confine myself to that proportion, as it admits of variation."

Almost the sole question in dispute was, whether the words "dry arsenic acid," in the first line of Mr. Medlock's specification, meant anhydrous arsenic acid, or whether they meant arsenic acid not wet or moist, but having in its constitution certain atoms of water. It was clear that anhydrous arsenic acid, or the acid freed from all atoms of moisture by exposure to heat, would not produce the effect desired when mixed with the aniline, and it was also clear that until the acid possessed as many particles of water as are contained in the constitution of what is popularly termed dry arsenic acid, the effects could not be produced. The evidence was extremely conflicting as to the proper meaning in chemistry of the word "dry," some scientific witnesses stating that it implied the removal of all water in combination, as well as any accidentally present, in which case the specification would be bad; and other scientific men asserting that it meant simply not in a wet or moist state, in which case Mr. Medlock would have accurately described the necessary ingredients in his process. The defendants relied upon another point—viz., that the term "dry" was ambiguous, and that the specification was, therefore, bad. The process of the defendants was to use the arsenic acid in solution when treating it with the aniline, and they contended that as dry arsenic acid was specified in Medlock's patent, their process was not an infringement. But the plaintiffs' counsel argued that any one, knowing the chymicals to be combined, might easily use one in solution and evaporate the surplus water, until it was practically in the same condition as if it had been used in a dry state, and that therefore no patent would be worth one farthing if it could be thus evaded.

The Lord Chief Justice, in summing up, directed the jury not to scan the specification in a spirit of hostile criticism, seeking to find out objections, but in the spirit of men desirous of understanding its meaning, and of using the knowledge which it contained. As to the question of infringement, if they were satisfied that the two processes used by the plaintiffs and defendants were substantially the same, their verdict would be for the plaintiffs, although it might have the curious result of giving to Mr. Medlock's patent a wider scope than the inventor himself intended, because it was Mr. Medlock's intention to caution the world to use the arsenic acid in a dry and undissolved state, and it was now found that it could be used in solution.

A Juror asked what their verdict ought to be if they were of opinion that the present process, though substantially the same, was an improvement.

The Lord Chief Justice said that no one, by superadding something, could deprive a patentee of his rights. The improvement might be the subject of a separate patent, but the discovery of the improvement would not give any right to use the substantial process without the licence of the original patentee.

The jury, having been locked up nearly two hours, and being unable to agree, were discharged without giving any verdict.

TO CORRESPONDENTS.

Received.—R. R., A. G., W. A., P. J. and Co., E. B. A., R. H., J. N., G. C. W., P. J. W., J. H. D., B. and Co., J. P. D., R. A., J. P. E.

An Apprentice.—The subject of your sketch, though ingenious, is scarcely suited for our columns.

Iron.—On page 378 you will find your question fully answered. You will get much information on the Motion of Projectiles out of a small work on this subject, by Major C. W. Owen; published by Mitchell, Charing-cross.

Cotton Gin.—We are often asked for our opinion on machines for this or that special work. However desirous we may be of obliging our correspondents, it will be evident that our publishing such opinions would lay us open to the accusation of interested partiality. Our advertising columns are open to questions like these.

Holywood, Belfast, Dec. 4, 1862.

In last week's Magazine, page 341, "The Atlantic Telegraph," ten lines from the bottom, 1,750 ft., ought to be 1,750 fathoms. R. Hoskyn.

Correspondence.

IRON WALLS AND NAVAL GUNS.

TO THE EDITOR OF THE "MECHANICS' MAGAZINE."

Sir,—Again we have the *irrepressible* Mr. Cheverton. He is doing his best to make wood backing as wearisome as he made the "Wave or Straight Line Theory." I should, as I intimated, have let the subject drop, but being invited to answer his arguments, I cannot refuse the task. Having committed myself to the advocacy of rigid *versus* elastic backing, I am bound to dispel the sophistries of a scientific writer, who inculcates an error detrimental to the public service. Every iron-cased ship with wood backing, taking the average expense of her armour, causes an absolute loss of £50,000. If we are to hold our own against the iron monsters of the deep in the service of other nations, our "Warriors," "Minotaurs," and "Caledonias," will have to be stripped of their armour, and made invulnerable at a new expense, so that the outlay on the present system is money thrown away.

Mr. Cheverton is so positive and pretentious with his demonstrations, that having founded them on false premises, as a man of science, he must expect no quarter.

In quoting my *dictum* that greater displacement, as well as greater strength, is attained in naval architecture with iron than with wood, the truth of which he does not deny—feeling that those few words refute his positive argument founded on the specific gravity of material—he has not the honesty to make that admission, but affects to suppose I misunderstood him. Nettled at this rebuke, he attempts to redeem his character, and at the same time to prove the superiority of wood to iron, by a statement referring to displacement, which is so palpable a blunder that, whether inadvertent or wilful, that it reflects equal discredit on a writer who pretends to be a public instructor and a reliable critic on naval construction. In scientific phraseology, he makes out a case after his own fashion, to the effect that iron backing, in lieu of 18 inches of teak, would be a "*cruel burden*" to a "Warrior;" and then, by way of proof, alludes to the lightness and buoyancy of teak, of which he says "the 4 or 5 feet under the water-line, not only bears up its own weight, but one-fourth or one-fifth more." Has he the simplicity to suppose that this natural effect of specific gravity is not well understood? And in lamenting the "cruel burden" of the iron, does he forget that the *positive* weight of the backing, whether in teak or in iron, will be the same? Counting the space which the teak occupied, he must know the displacement and the burden will be equal quantities.

To make good his point, which Mr. Cheverton dilates upon as evidence of his acumen, *he shifts the question by shifting the line of measurement, which determines displacement.* He assumes two different breadths of beam, varying with the thickness of the iron and wood backing, whereas to institute a fair comparison, he should in both cases take the breadth of beam, as it really is, to be the same. There is, then, no more burden with the iron than with the wood backing, the buoyancy is the same; and there is an absolute gain in stowage or deck room, to the extent of the difference between the thickness of the teak (18 in.), and its equivalent in iron 2 in., or a difference of 16 in. on each side of the vessel, making 2 ft. 8 in. more available width between the broadsides in favour of iron.

With this light thrown on the subject, what becomes of the triumphant exclamation, that "it is *obvious at a glance*, that for all which is under water, wood is a relief and iron is a burden to a ship." If a schoolboy, in his first apprehension of specific gravities, gave utterance to this statement, we should smile, and tell him, it was true in respect of solid masses of the two materials, but quite erroneous when they come to be moulded into certain forms, adapted for flotation, for which iron, by its ductility and strength, is far more suitable than wood; and, telling him the story of the wise men of Gosham, we should inform him, that they might swim more safely in a bowl of iron than in a bowl of wood.

To illustrate the absurdity of Mr. Cheverton's method of arriving at his erroneous conclusion, we will take a cubic foot of wood and its equivalent weight in iron plate. We form the latter into a vessel containing one cubic foot, and we demonstrate that, weight and volume being the same, displacement and buoyancy are the same. As an answer, Mr. Cheverton takes a hammer, beats the iron vessel into a mass, throws it into the water, and, with childish glee, shows the metal will sink. But this is a juggle—a pitiful evasion of the truth. By altering the volume, he alters the measure of displacement. In vain will he exclaim that I misrepresent him, but I do not. In attempting to prove that by using 2 in. of iron in lieu of 18 in. of teak as backing to the armour plates of the "Warrior," "the iron defence would

be a cruel burden upon the buoyancy of the ship," whilst the teak would be a relief, he practically has recourse to the juggle I have exposed. In a verbiage, betraying an inexplicable confusion of ideas, he commits blunder upon blunder, "Equal weight," he says, "will give equal displacement." I have shown that volume must be combined with weight, to work out the problem of displacement. Next he says, "the question is not about the weight of the hull of a ship in relation to its strength and capacity, but about its weight in relation to penetrative resistance to shot," and then he reiterates the same idea in three or four other forms, which I need not quote. But again he betrays ignorance of the subject, for the chief aim in the construction of iron-cased ships is, to effect precisely that which the clever critic declares is not the question. The real problem to be solved is how to apply the iron which constitutes the armour, in such a way as that it shall be a *principal element* in the structure of the ship, that it shall add to its strength and capacity, and "that its weight and substance shall offer the greatest penetrative resistance to shot." This he evidently does not understand, and is so wedded to wood, and apparently so incapable of comprehending that a ton of iron fashioned into the form of a vessel, is practically more buoyant, whilst it is much stronger, that it is useless to argue with him; and, truth to say, I am not trying to convert him, but to demolish his mischievous advocacy of wood as a resisting medium to projectiles.

Referring to the comparative resistance of iron and wood, Mr. Cheverton, to support his view in practice, is driven into the absurdity of proposing increased thickness of wood. Thus, in constructing a floating battery, calculated to resist the heaviest guns, if 15 inches of iron were requisite, he woutd cover each side of the vessel with its equivalent—12 feet of timber—making together 24 feet, *versus* 2 feet 6 inches of iron, reducing the available width of a deck of 50 feet beam to 26 feet. In the uncompromising fervour of his love for wood, he would even construct her solid of that material, from broadside to broadside, rather than abandon a principle.

He quotes my description of the effect of shot on the centre of a plate backed with wood, by causing it to dish where struck, and buckle at the extremities, as a proof that wood prevents penetration. But the effect described is quite beside the penetration question: it illustrates the disadvantage of wood in causing the destruction of the fastenings; but, nevertheless, the distortion of the plate does not save it from being perforated. The two effects proceed from the same cause, the yielding nature of the material, whence it arises that the iron is more easily penetrated as well as more easily distorted, than if it were fixed on a rigid backing.

I am as precise in my view of penetrative effect as the severest theorist or logician could desire, and do not seek to evade absolute conditions. But Mr. Cheverton does; he will not fix his mind on the difference between penetrating and crushing effect. The former is purely *local*, and with a rigid backing may be limited to the area of impact; whilst with a yielding backing, not only is penetration made more easy, but the crushing effect is more disastrous. Prevent penetration—stop the shot—you break it up, or hurl it back, and you exclude the foe. The art of constructing invulnerable armour, consists in resisting penetration. This will never be effected by the outer shield—the armour plate proper—unless it be bedded on rigid backing. This law, for as such I regard it, was, in my opinion, settled by the comparative trials on plates of the same thickness, with various backings. The *absolute condition* in those trials was a plate 2½-in. thick. The problem was "will the plate resist penetration best with a rigid or an elastic backing?" The answer by the effects produced was decisive, and is a positive negative to the elastic theory, which practically maintains that you can punch a hole through a plate on an anvil easier than on a block of wood.

When Mr. Cheverton says that iron backing is virtually a variation in the thickness of the plates, he has recourse to that plausible evasion termed "begging the question," and he furnishes the best proof that he is at a loss for a fair logical argument and practical demonstration. At the same time, as it not unfrequently happens to disputants who are predetermined, as he is, not to relinquish a theory, he has unwittingly produced an argument which demolishes his own case. Precisely as he says, the rigid backing does *virtually add to the thickness of the plate*, and thus it prevents penetration. My thanks are due for this curt and happy definition of the principle of rigidity. One more remark and I have done. Given, a thickness of plate, which, without any backing, can be penetrated by a certain force, an inch of *iron* backing will prevent penetration; but, the force being the same, *no thickness* of wood backing will save the plate from penetration. Let Mr. Cheverton and the other advocates of wood backing ponder over that proposition, and if they cannot prove it to be untrue, let them honestly confess they are beaten.

I must not dismiss Mr. Cheverton without alluding to his eccentric idea of soldering iron plates in one mass over the hull of a ship. He calls the process bronzing, and tells us it may be carried into practice; but the scheme is visionary, and, if it were practicable, the result would be that a few broadsides on this tortoise-shell covering would shiver it to pieces, causing long and deep cracks, and strip it off in large fragments.

I have, I fear, been prolix, and at too much pains in refuting Mr. Cheverton. We don't break a butterfly on a wheel, but small obstructions sometimes require an effort to remove them. A writer who affects to govern opinion on a question involving national interests, and who, regardless of reasonable correction, persistently propogates error to the detriment of the public service, must not be dealt with tenderly.

CIVILIAN.

"WHOSE IS MR. WHITWORTH'S GUN?"*

Sir,—The writer of the article which appeared in your paper of Nov. 15th, asking "Whose is Mr. Whitworth's gun?" has evidently been misinformed as to the real facts of the case.

A portion of the correspondence with reference to the construction of that gun (the 7 inch gun lately fired at Shoeburyness), took place between Mr. Anderson, of Woolwich, and ourselves as a firm: during a part of the time occupied in its construction, Mr. Whitworth was prevented by illness from giving it attention.

We shall feel obliged if you will give us an opportunity of stating simply what are the real facts and how they occurred. Your readers will then see that the writer of the article must have been misled by incorrect information.

At the latter end of last year, Mr. Whitworth requested permission to have a heavy gun (7 in. bore) made on his plan at Woolwich, in order that he might try upon a target, like the "Warrior," the effect of shells he proposed to make. The reason for making this application was simply that our works in Manchester were not at that time in a position to make a gun of the required size. The facilities for doing it existed at Woolwich, and similar permission had previously been asked for and obtained by several other persons.

December 7th, 1861, Mr. Whitworth was informed that the War Office sanctioned the manufacture at Woolwich "of a 7-inch gun made according to your (Mr. Whitworth's) principles, and made under your directions."

Mr. Whitworth, a few days after, came to London, and arranged for the manufacture of the gun. Soon afterwards, we sent to Woolwich a drawing of the gun proposed to be made. Its breech was closed by a screw, of a kind not, we believe, previously used, except by ourselves in our 70-pounder guns. It is a triple screw, having three different diameters on a common axis; these take simultaneously into three internal screws, the smallest fitting in the end of the bore, the other two screwing each into the end of a hoop, of a kind not, as we believe, previously used, except by ourselves in our 70-pounders. It is a screw having three different diameters on a common axis.

Instead of this screw, Mr. Anderson proposed to use a tube closed at the breech end, and sent, Dec. 19, 1861, us a drawing of a gun, finished to the outlines of your (Mr. Whitworth's) drawing, and showing the modifications founded upon it which he suggested.

Mr. Whitworth's partner, Mr. Hulse, then went to Woolwich, and conferred with Mr. Anderson upon the modifications suggested, and a third drawing was the result. We subsequently supplied, upon request, the necessary gauges, and sent written directions as to the bore, rifling, windage, &c.

We refer to these details, merely to show that we were in constant communication with Mr. Anderson during the construction of the gun, and that it was made as originally directed by the War Office, "according to Mr. Whitworth's principles, and under his directions."

After this explanation, it cannot be said that Mr. Whitworth was in error when he stated, in his letter to the *Times*, that his 7-inch gun was made according to drawings supplied by him or his firm.

He expressly acknowledged the ready and valuable assistance received from Mr. Anderson. He also stated that he should feel pleasure in making similar acknowledgments to Sir William Armstrong, if he would point out what invention of his had been used in its construction. This, neither Sir William nor the writer of the article in your paper has done.

In no respect whatever, as far as we are aware, was any suggestion ever made, or any advice given, by Sir William Armstrong as to the construction of the gun; nor has he in any way whatever had anything whatever to do with it, or the drawings from which it was made.

But it is said that the gun was made on the coil principle, and therefore Mr. Whitworth was indebted to Sir William Armstrong. This obliges us, in order to prevent further misapprehension on this point, to state very shortly something of what was known of the coil principle in this country before the Armstrong gun was introduced.

We avoid making allusions to the claims that may be put in by contemporaries, and will refer to the well-known published accounts of those who, as Mr. Whitworth said, "were equally predecessors of Sir William Armstrong and himself."

The Blue-books of the Patent Office describe the methods of making guns employed between the years 1830 and 1850, by Richards, Horton, Aspinwall, Cowper, and others; all these adopted the coil principle for the manufacture of ordnance of various calibres.

We will take one case, as it is perhaps necessary to show that these were not mere crude suggestions, but that full descriptions are given both of the method of making a gun on the coil principle, by welding cylinders formed of coiled bars, and of the machinery employed in the coiling and welding process.

We will, therefore, refer, as an example, to the method adopted, and very fully described with drawings, by Mr. Aspinwall. (See Blue-book Specification, No. 10,013, January 16, 1844.)

He says, page 2, line 21, his "improved cannon are formed of wrought iron or steel, first formed with separate rings, or short hollow cylinders, which are joined together end to end." The rings are formed, pp. 12, 13, 17, by "winding a bar of iron or steel in a spiral form, by winding machinery."

The ring so made is heated in a furnace, and welded to form a cylinder by end pressure.

Sir William's first gun was made, we believe, in 1855. His application for a patent for his gun was made in February, 1857.

Mr. Whitworth, in the specification of his patent of December, 1854, describes guns made of segments and hoops, which, he says, may be put on in a second series. The hoops used by Mr. Whitworth were made of welded coiled iron. He may, therefore, be said to have anticipated

* From the *London Review*.

Sir W. Armstrong in using the coil principle, though we fully admit that others preceded him.

The cylinders so formed are heated and connected end to end, by welding them also by pressure, which is given, "by hydrostatic or hydraulic press, or screw press, or any other press" (p. 11).

Such being the method of using the coil principle for making guns previously adopted (and to which we have in self-defence been compelled to allude), Sir William Armstrong used it, as he was entitled to do, in his way for his purpose.

So far from wishing to detract from what was due to Sir William Armstrong, Mr. Whitworth freely admitted that he was entitled to full credit "for practically carrying out the system." That admission did not, however, shut out Mr. Whitworth from using, like Sir William, that which the predecessors of both had employed, and for that reason he asked Sir William to point out what invention of his had been used in making the Whitworth 7-inch gun.

The writer of the article also asks if Mr. Whitworth claimed the invention of the solid bar for the inner tube? Certainly not; it was well known before.

But it must be admitted, that while Sir William Armstrong has advocated the use of cylinders formed of welded coiled bars united end to end, like Mr. Aspinwall's, Mr. Whitworth has deprecated their use, and we have always used a solid bar of homogeneous metal, bored out, for the inner tube of the guns made out at our works. He was therefore justified in pointing to this distinction without meaning to claim the use of the solid bar as an invention.

With regard to the evidence of the president of the Ordnance Select Committee, General St. George, quoted in your article, stating that Mr. Whitworth "found that homogeneous iron did not answer for large guns," we can only say that every large gun we have made has had its inner tube of this very iron, and that we are now making them entirely of that metal, as we have always made our field-guns and rifle muskets.

We cannot close this letter without expressing our great regret that the success of Mr. Whitworth's late trial appears to have called forth a feeling of animosity which we have no desire to reciprocate.

While we are compelled to reply to unfounded statements, we desire to do so with all courtesy, and without detracting from the merit which we acknowledge to be due to others.

We are, Sir, yours very obediently,
The Manchester Ordnance and Rifle Company.

28, Pall Mall, Nov. 27, 1862.

FOREIGN LOCOMOTIVES.

Sir,—In your notice headed "The Foreign Locomotives in the International Exhibition," at page 325 of your journal, for November 21, you give a description of an Austrian engine, called the "Duplex," and couple with it the observation that, "the way in which the complete balancing of the parts has been carried out, is to some extent a renewal, *in a much improved shape*, of an invention of that veteran schemer, Mr. L. R. Bodmer, of Switzerland, &c." (should be Mr. John George Bodmer.) You also explain very correctly that, according to Mr. Bodmer's plan, the cylinder of an engine had two pistons, and two piston-rods working one within the other, with a connecting rod to each; the pistons alternately advancing towards, and receding from each other in the cylinder. And you conclude, by saying that there are one or two large engines upon this plan still extant in the Lancashire districts; that they require occasional "doctoring up;" and that one of the weak points of the latter arrangement consists, of course, in the tubular outside piston rod, which continually causes trouble, particularly from the necessarily weak attachment of the piston.

Having seen the whole of the engines made by Mr. Bodmer, from the first to the last, in operation, I hope you will excuse me if I take the liberty of making a few remarks upon the statements made by you in regard to them.

In the first place allow me to observe that the object Mr. Bodmer had in view in "scheming" and carrying out the double piston or compensating principle, was to confine the strain arising from the pressure of the steam, on the one hand exclusively to the cylinder, on the other hand exclusively to the piston and connecting rods, and to the cranks. Now, as soon as two cylinders are employed, the compensating effect becomes partially neutralized, and the framework and foundation of the engine must suffer in a corresponding degree; and in the case of a locomotive engine, an injurious lateral, as well as an oscillating and reciprocating motion, must be the consequence.

That these defects are reduced to some extent by placing the cylinders as closely as possible together, I admit; but I am somewhat at a loss to understand how, in point of implicity, there can be an advantage in aving *two* cylinders, *besides* the double set of pistons, piston rods, and connecting rods.

I do not remember that the mode of attaching the piston to the tubular piston rod proved to be an objectionable feature in Mr. Bodmer's engines; nor am I aware that there is anything in the nature of a hollow piston rod to prevent its being made just as solid and substantial as necessary at the point referred to, as well as at any other point. It is, no doubt, a drawback to have two connecting rods of unequal lengths, and perhaps the slight extra wear and tear, owing to this peculiarity of construction, may, to some extent, justify the insinuation of the "doctoring" required. But, Sir, the double piston principle is quite independent of tubular piston rods and connecting rods of unequal lengths, and can be carried out in all its integrity, if need be, by the use of the most old-fashioned and ordinary, and therfore, of course, perfectly trustworthy and safe means of connecting the piston with the crank.

The majority of those of Mr. Bodmer's compensating engines, which are, at the present day, at work in Lancashire, are of 60-horse power, and non-condensing. And it may not be uninteresting to some of your readers to know, that they are of the inverted cylinder kind; that the crank-shaft, which is of cast iron, makes 120 revolutions per minute, and that the foundation consists simply of a few feet of brickwork. So complete is the counterbalancing effect of the double piston system that the pedestal caps can be removed and the engine worked at its usual speed without the crank-shaft being in the least displaced.

Steam-engines capable of working at great speed without involving undue wear and tear, are now urgently wanted, especially for screw propellers. Mr. Bodmer foresaw that such a time would come; and I venture to suggest that some of those engineers who make the steam-engine their speciality, instead of putting themselves to the trouble, inconvenience, and expense of attempting to balance the action of their engines by pressing into their service two, three, and even four cylinders, in all conceivable positions, should for once try Mr. Bodmer's far more simple and thoroughly efficient plan. That gentleman has now been so long absent from England that I feel convinced nobody would blame such enterprising engineers for adopting one of his ideas, even if such adoption happened to be accompanied by an open acknowledgement of the source from whence that idea was derived.

There can be nothing startling in the idea of having two pistons, each traversing only one-half the length of the cylinder; there is nothing new or startling in having two or more connecting rods acting upon the same crank-shaft; there is nothing new or startling in making a crank-shaft with cranks placed exactly opposite to each other; and now-a-days, engineers have so much knowledge and experience of their craft, and such appliances for producing accurate workmanship, and for carrying out the most difficult operations, that it would be an insult to them to suppose that they could not find means of dispensing with the tubular piston-rod, if they chose, and still more so, that they could not "scheme" one which would necessitate "no doctoring."

That the double piston principle answers the purpose for which it was intended by its inventor, is unquestionable; and an inspection of one of Mr. Bodmer's engines would, I feel sure, convince an engineer of this fact—the tubular piston-rod, and the long and short connecting-rods, notwithstanding. I am, Sir, &c.,
T. R. Bodmer.

MULLEY'S AUXILIARY RUDDER.

Sir,—I copy from the last month's *Naval Chronicle* a part of the experiments which were made on board H.M.S. "Cordelia," at Plymouth, for the trial of Mr. Mulley's new invented auxiliary rudder. In order to save your space I only make allusion in *italics* to the two experiments which were considered inexplicable to all who witnessed them.

Here follows what I have copied from the *Naval Chronicle*:—"*The auxiliary, tried alone, was found not in any degree to affect the ship's course*;" this was attributed, in some measure, to the fact that the "Cordelia" is supplied with a left-handed screw.

The helm and the auxiliary being both put to starboard, the circuit occupied 7 *minutes* 37 *seconds, the auxiliary thus retarding instead of assisting the revolution.*

The first experiment in *italics* is by far the greatest puzzle, but may be unriddled thus:—The auxiliary rudder (or what may be termed the *fin*) being put over on the starboard side, and the rudder amidships; the fin thus cuts off the current from the starboard run of the ship, whilst the current is acting with its full force on the port side run of the ship, and afterwards is directed upon the port side of the rudder; these current opposing forces neutralize all the turning qualities of the fin.

The other turning experiment, also shown in *italics*, is more easily comprehended and explained; both the rudder and the fin having been placed in the same direction (say on the starboard side), the cotter (the fin) becomes a screw to the former, cutting off a current which otherwise would be directed with its full force on the starboard run of the ship, and would be equal to the force of the current on the opposite side, not only that, but when the current had passed the run, not having any current to meet it, would naturally impinge itself on the port side of the rudder, notwithstanding its position, and thus these two forces, acting in a contrary direction to that supposed to be produced by the fin, would neutralize all the good qualities which the inventor had reckoned upon.

If the fin were placed at the head of the ship instead of in close contact with the rudder, and both placed in opposition to each other, then the greatest result in turning power would be effected in accordance with the inventor's conception.

It is with the greatest diffidence that I make the attempt of solving a riddle which has been deemed inexplicable by those who witnessed the experiment on board the "Cordelia." Should my explanation be deemed obscure without any aid from diagrams, I shall be ready to furnish them should they be required. I am, &c.,
Molyneux Shuldham.

Dec. 8th, 1862.

GIFFORD'S INJECTOR FOR AGRICULTURAL BOILERS.

Sir,—We are glad to see that you advocate in your journal the adoption of Gifford's injectors on agricultural boilers, for which purpose they are indeed admirably suited.

One superiority the injector possesses over the pump is, that the boiler can be filled by it at such times as it is not convenient to run the engine, and when steam is therefore probably blowing off, as at meal times.

Moreover, when supplying the boiler, the injector not only forces in the water, but, at the same time, heats it to a high temperature (which varies with the pressure at which the boiler is worked), while the feed-pump, on the other hand, sends the water into the boiler, but without in the least degree increasing its temperature. With these considerations in view, it will be seen that economy of fuel may be obtained by the use of this instrument.

Again, having no parts in motion, such parts being liable at all times to get out of repair, and, therefore, requiring to be replaced, it commends itself in districts where skilled mechanical labour is scarce, such as those in which portable agricultural engines are generally employed; and the continual expense of keeping a pump in order is thus entirely avoided.

The method of working the injector is, moreover, so easily learnt, that no difficulty arises in teaching its use to men not thoroughly conversant with machinery generally.

The great majority of explosions that occur to agricultural boilers take place, directly or indirectly, from the want of water. The attendant, not being able to feed the boiler at meal times with the ordinary pump, finds the necessity of water when he comes to start the engine, puts on his pump, the water injected on a hot fire-box flashes into steam, and away goes the boiler. Of course, a careful man would drop his fire and cool the fire-box; but he would surely be abused by the farmer, inasmuch as the whole gang of labourers would

stand idle. The result is, the attendant runs the risk, and every few weeks a sad accident follows.

Now, with the invention of the injector, there is no excuse for this class of accidents, and it seems to be the duty of the press to warn the public on the point.

You will ask, why do the manufacturing engineers allow this state of things? The answer is, because the injecter adds to the price of the engine and boiler some £8 or £10, and they compete so keenly with one another to produce the cheapest article possible, that they are afraid to see their names attached to anything but the lowest prices.

For a 10-horse power portable boiler, working at about 90 lb. pressure, we think a No. 3 injector would be sufficient; the price you will see from the inclosed prospectus.

We shall be very glad if you find the above remarks to be of any service to you,

And are, Sir, yours obediently,

SHARP, STEWART, & Co.

ELECTRO STEERING APPARATUS.

SIR,—I see a notice in your MAGAZINE that "a Mr. Gisborne has taken out a patent for an electric communication with the helm, &c." Allow me, Sir, to tell him, and the public, through your columns, that Mr. Graham Gilmore invented the electric steering apparatus more than *five* years ago; that he had it in use on board a steamer he commanded for two years, that it has been fitted to H.M.S. "Resistance" for more than three months, that it was to have been fitted more than four months since to H.M.S. "Black Prince,' but she sailed unexpectedly for Gibraltar; that the existence of the apparatus was well known to the nautical public, to Capt. C. Coles, R.N., and Capt. Fishbourne, R.N., and to many other naval officers a long time ago; that we are working our telegraph, the firm standing as Gilmore, Preece, Gilmore, and Co., and that we disclaim against Mr. Gisborne having the slightest right, not only to a patent, but to any credit for the invention of "Gilmore's Electric Steering Apparatus."

Trusting you will kindly insert this in your MAGAZINE, I am, &c.,

ARTHUR H. GILMORE,
pro
Gilmore, Preece, Gilmore, and Co.

Woolston, near Southampton,
Dec. 3rd, 1862.

WAS THE FOLLOWING AN INVENTION OR NOT?

SIR,—When quartered with my late regiment, the 34th, at Galway, in 1827-28, I pierced the front side of a steel cuirass, which is formed with an incline, so as to throw spherical shot aside, by firing a flat-faced steel punch against it, from a Standenmeyer rifle air-gun. I previously fired at it, from the same gun, a cylindroconoidal steel punch, but the cone formed front of the punch caused it to glance off without leaving any perceptible indentation. I published this fact several years ago, although I do not now recollect in what publication. I had not, at that time, seen the old English war arrow, with its steel punch-formed, flat-faced head, which was (about six years after) presented to me by a brother toxopholite, the late Mr. Roberts, author of "The English Bowman."

J. NORTON.

Royal Marine Hotel, Bray.

INITIAL AND IMPACT VELOCITIES OF PROJECTILES.

SIR,—If any of your correspondents can supply a diagram and description of the apparatus for determining the initial and impact velocities of projectiles, which is now in use at Shoeburyness, many of your readers will be very much obliged.

5, Keynsham-parade, Cheltenham.

Gossip.

Some time since we called attention to C. S. Duncan's patent for applying Ratan cane, as a substitute for iron, in the manufacture of submarine telegraph cables. Certainly this substance possesses many qualities essential to a good cable, and just now, when there is a likelihood of another Atlantic cable being laid, it is desirable that Ratan cane should be considered and experimented upon. There can be no doubt of its lightness, flexibility, and strength, but we are not sure that "marine insects will not touch it." Perhaps Dr. Wallich, or Professor King, could throw some light upon the subject. When it is decided to lay another Atlantic cable, we hope the company, for the sake of the great interests involved, will not commit itself to any cut and dried scheme, without exhaustive inquiry. There was too much precipitancy and exclusiveness in laying the first cable, and we find a lingering prejudice in many minds as to the result. We hope, therefore, that not only Ratan cane will have due consideration, but every honestly suggested experiment.

On the 28th ult. we drew attention to a regulation just then issued from the department of the Controller of the Navy directing that the Kynaston disengaging hooks were to be in future fitted to the stern and quarter boats of all ships brought forward for the first class steam reserve, and for commission, and which order virtually excluded from the service Clifford's boat-lowering apparatus, by which so many lives have been saved at sea, both in the Royal and Mercantile Navies. In consequence, the subject was brought prominently before the Lords of the Admiralty, and their lordships have written to Mr. Clifford, officially, to inform him that the captain of any of her Majesty's ships, on applying for his boat-lowering gear, is to be supplied with it as heretofore. It is to be hoped that this decision of their lordships will not be rendered nugatory by contrary orders issued from the office of any subordinate department.—*Times.*

A number of Armstrong 40-pounder and 100-pounder wedge guns are in course of manufacture in the Royal gun factories, at Woolwich, at present; and at Elswick, Sir William Armstrong is engaged in testing a number of 100-pouuder guns in preparation for the forthcoming important competition between the two rival manufacturers, his own and Mr. Whitworth, to take place at Shoeburyness. The Select Committee of Woolwich Arsenal have received instructions to attend the trials, and deputations of the Royal Artillery and Royal Engineer officers have been invited to be present. The result of the experimente will, doubtless, go far to decide the relative merits of each gunmaker, and they are, consequently, looked forward to with much interest, and are commented upon freely.

A WONDERFUL BALOON !—*Galignani* describes a newly-invented balloon as being very wonderful :—"The new Montgolfier baloon, invented by M. Godard, the aëronaut, has a capacity of 4,300 metres. The car is provided with an apparatus which enables the aeronaut to ascend without either gas or ballast, and to descend or go higher up at pleasure. This apparatus consists of a kind of stove formed by three cylinders, separated by insulating substances, whereby all danger of fire is averted. The flame is completely under the control of the aerial traveller, and is prevented from rising too high by a cap of wire gauze. M. Godard asserts that he can inflate his baloon in 30 minutes, and load it with from 600 to 800 kilogrammes over and above the weight of his person and his accessories, and, moreover, that his balloon may be pierced with a bombshell without endangering the aeronaut, who can himself cast projectiles of any kind with impunity. Should this new invention succeed, this balloon may be of considerable service in time of war."

THE WINANS' CIGAR STEAMER.—According to a correspondent of the *Scientific American* the Winans' cigar steamer is at the wharf of Messrs. Winans at the ferry-bar, at Baltimore, as harmless as a dove, without any intent of running the blockade to act as a ram for the confederates; but as far as he could learn she was built for nothing but an experiment, as the Messrs. Winans are now building one in London, the same plan of hull, 700 ft. long, with screw propellers, one fore and aft, instead of the wheel surrounding the hull amidship as in the present one. The larger vessel was to be built here, but our national troubles put a stop to it. There is also a water tank here, the same shape as the steamer, which was intended to bring salt water from sea to be used in experimenting, as there was an engine and boiler put up on the wharf for the purpose; but unfortunately for science, on her first trip, the tank was captured by the Government officers at Fortress Monroe; but through the intervention of General Dix it was released. Under these circumstances the Messrs. Winans thought it better to spend their money in a foreign land.

GAS LIGHT IN RAILWAY TRAINS.—It is highly to the honour of the Scottish Central Railway, that it has, of all the railways of Scotland, initiated a movement, the first steps in which ought to have been long ago taken. It is somewhat singular that of all the improvements which have been effected by science in the ordinary conveniencies of life, during the last half century, so little has been done to secure comfort in railway travelling. Of the requisites, none is of more importance—as those who are in the habit of making long journeys are well aware—than a system by which a clear and equable light may be obtained. The filthiness, the dimness, and the expense of the ordinary oil lamps cannot be excused in so great a scheme as a railway. The Scottish Central train which left Edinburgh for the north, on Monday night, was brill antly illuminated with gas, and the trial has been so successful that, so far as regards this particular line and train, it may be looked upon as a *fait accompli*. The gas is supplied from a large boiler at the Perth station, which is filled from the gas-works there. The supply for the train is kept in an india-rubber gasometer of about six feet square, defended by iron rods, and kept in a compartment of the break-van. When full it occupies the whole of this compartment, but as the gas passes away it is compressed by a weight on the top. The gas is conveyed into it, from the boiler, by a large tube in the bottom of the van, and is conveyed out of it to supply the carriages by a smaller tube, also in the bottom. This tube again passes up through the anterior part of the van to the roof, and the gas is thence conducted along the carriages by metal pipes, connected by india-rubber tubing, and passes down by brackets into large and strong glass globes in the various divisions of the carriages. The supply necessary for the double journey to Perth and back, which occupies somewhat less than eight hours, is about 260 cubic feet; and the expense, after the fittings are completed, is estimated at one-half of that of the ordinary oil apparatus. The only objection to the scheme is that it must be confined, except with great difficulty and expense, to trains which do not require to be taken down, such as those for long journeys, and express trains; but, as it is in these that light is most required, the objection is not a strong one. The system has been for some time in operation on the Lancashire and Yorkshire, and London and North-Western Railways, and was introduced on the former line by Mr. Newall, inventor of the patent break. The honour of introducing this great improvement into the Scottish railway system belongs to Mr. Allen, of the Scottish Central line.—*Caledonian Mercury.*

Patents for Inventions.

ABRIDGED SPECIFICATIONS OF PATENTS.

THE Abridged Specifications of Patents given below are classified, according to the subjects to which the respective inventions refer, in the following Table. By the system of classification adopted, the numerical and chronological order of the specifications is preserved, and combined with all the advantages of a division into classes. It should be understood that these abridgments are prepared exclusively for this Magazine from official copies supplied by the Government, and are therefore the property of the Proprietors of this Magazine. Other Papers are hereby warned not to produce them without an acknowledgement :—

STEAM ENGINES, &c., 1468.
BOILERS AND FURNACES—*none.*
ROADS AND VEHICLES, including railway plant and carriages, saddlery and harness, &c., 1430, 1445, 1467, 1485, 1492.
SHIPS AND BOATS, including their fittings, 1424, 1425, 1434, 1436, 1448, 1460, 1463, 1466, 1470, 1477, 1493.
CULTIVATION OF THE SOIL, including agricultural implements and machines, 1459.
FOOD AND BEVERAGES, including apparatus for preparing food for men and animals, 1411, 1441.
FIBROUS FABRICS, including machinery for treating fibres, pulp, paper, &c., 1421, 1427, 1428, 1452, 1457, 1464, 1475, 1489.
BUILDINGS AND BUILDING MATERIALS *none.*

LIGHTING, HEATING, AND VENTILATING, 1413, 1414, 1418, 1439, 1440, 1483.
FURNITURE AND APPAREL, including household utensils, time-keepers, jewellery, musical instruments, &c., 1412, 1442, 1446, 1449, 1451, 1456, 1461, 1465, 1474, 1476, 1480, 1486, 1488, 1491, 1495.
METALS, including apparatus for their manufacture, 1422, 1447, 1473, 1484, 1487.
CHEMISTRY AND PHOTOGRAPHY, 1453, 1496.

WARFARE, 1417, 1454, 1458, 1478, 1497.
LETTER-PRESS PRINTING, 1490.
MISCELLANEOUS, 1415, 1416, 1419, 1420, 1423, 1426, 1429, 1431, 1432, 1433, 1435, 1437, 1438, 1443, 1444, 1450, 1455, 1462, 1469, 1471, 1472, 1479, 1481, 1494, 1498.

1411. E. KOLBENHEYER. *An improved apparatus for making ices and cold beverages.* Dated May 10, 1862.

This consists in arranging apparatus so that, by a winch handle, with suitable gearing and proper connecting and working parts, a rapid evolving motion may, with the utmost facility, be imparted at pleasure, either to an inner vessel turning on a proper pivot, and inserted in a pail or outer vessel, or to a suitable stirring apparatus contained in the said inner vessel, which latter is to contain the cream or beverage to be cooled down, or to be made into ice, by the effect of the ice or other frigorific mixture contained in the outer vessel. *Patent abandoned.*

1412. J. B. CRISTIFINI. *An improved tent.* Dated May 10, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1413. W. CLARK. *Improvements in lamps, and in apparatus for filling lamps with oil and fluid to be consumed.* (A communication). Dated May 10, 1862.

We cannot here give space to the details of this invention. *Patent abandoned.*

1414. H. W. SAWBRIDGE. *Improvements in sliding chandeliers, gasaliers, and other pendent lamps.* Dated May 10, 1862.

This consists of improvements in the slides of such pendent lamps as are required to be raised and lowered at will; and for gas pendents the patentee also dispenses, with the use of water, by the following means:—The inner tube, which in gasaliers convey the gas to the body of the lamp, he removes altogether, substituting in place thereof, a tube of vulcanised india-rubber, containing a spiral spring if requisite. The upper end of this rubber tube is secured to a nozzle inside the cap of the usual ball joint, or to the top connection or neck, which may be used in place of the ball joint. The lower end of the tube is connected under the pommel of the outside down rod, by a similar nozzle or flanged collar. In case of the breakage of the balance chains, the rubber tube prevents the lamp from running down, and if it be applied to a gasalier there is no escape of gas. *Patent completed.*

1415. H. WALKER. *Improvements in making handles for crochet needles, pencils, penholders, and other articles.* Dated May 12, 1862.

The documents relating to this invention cannot at present be seen, an extension of time for filing the final specification having been allowed.

1416. MILNES. *Improvements in portable apparatus for exercising the human body.* Dated May 12, 1862.

This improvement is not described apart from the drawings. *Patent completed.*

1417. G. FUHRMANN. *Improvements in melting and boring cast steel barrels, applicable to fire-arms and pieces of ordnance.* (A communication.) Dated May 12, 1862.

This consists in introducing into the centre of the piece or ingot to be cast, in the mould or ingot mould, a core, composed of any malleable metal easily pierced by a drill or boring instrument. This core naturally forms one body with the steel thus cast, spreading with it in the subsequent operations of forging and rolling, but always preserving the central point, and a diameter which will suffice for the ulterior work. *Patent completed.*

1418. CLARK. *Improvements in smoke-consuming fire-grates.* (A communication.) Dated May 12, 1862.

This relates to a smoke-consuming grate, in which the fresh fuel is supplied underneath that already in ignition, For this purpose the grate is made moveable, and has a rotating motion imparted to it; it is made somewhat in the form of a cylindrical cage, suitable for the purpose. *Patent abandoned.*

1419. I. B. POPE. *Improvements in apparatus for lowering and loading coals, minerals, or other substances.* Dated May 12, 1862.

Here the waggon or carriage containing the coal or other material, is carried on rails from the mouth of the pit or other situation on to the tipper, which is connected to a moveable stage suspended from a pivot, the point of which stage may be lowered gradually by an ordinary spring brake, at the same time that the tipper is upset on the release of its break, the front of the stage being raised to its original position (after the waggon or carriage has discharged its contents) by counter balance weights. The usual screw, which is vertical, has arms mounted on fixed centres in the framework of the moveable stage, and is moveable on its centres so as to become inclined when pressed forwards by a projection on the front of the waggon or carriage, or by the pressure of the waggon when upsetting, but is restored to its vertical position on the removal of such pressure by a counter balance weight. The patentee also uses a horizontal screen in the floor of the swinging stage, a lid specially constructed being connected to the tipper. By this combination of apparatus, the coals or other materials are tipped and lowered gradually, as required. *Patent completed.*

1420. C. J. HARRIS. *Improvements in the manufacture of detector, season, and non-transferable tickets.* Dated May 12, 1862.

This consists in the application to, or combination with, each of such tickets of a photograph portrait of the holder thereof. *Patent abandoned.*

1421. H. S. FIRMAN. *Improvements in apparatus for washing and cleansing textile fabrics or raw materials, and for forcing fluids or moisture from the same.* (A communication.) Dated May 12, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1422. J. H. JOHNSON. *Improvements in casting metals, and in the moulds and cores employed therein.* (A communication.) Dated May 12, 1862.

This relates to certain arrangements of moulds and cores to be used in casting metals, but is more particularly applicable to the casting of the units of the peculiar steam generator, for which letters patent were granted to the present patentee the 30th August, 1859 (No. 1970), and consists of certain peculiar arrangements and constructions of moulds and cores, and in the mode of combining the same, whereby greater accuracy in the casting is obtained, with allowance for shrinking in the casting. The moulds are made in several parts, which are made up either entirely of metal and partly of sand, or other heat-resisting and porous material, the several parts being in all cases so disposed as to allow for the contraction of the casting when cooling, and, if necessary, prevent chilling or hardening of those parts of the casting which are afterwards to be worked, facility being also afforded for the accurate adjustment of the core inside the mould. *Patent completed.*

1423. H. BAYLEY, L. NEWTON, and J. GREAVES. *Improvements in machinery for turning, boring, cutting, shaping, and reducing wood and other substances applicable for the manufacture of various articles.* Dated May 12, 1862.

We cannot here quote the details of this invention. *Patent abandoned.*

1424. H. CARTWRIGHT. *Improvements in propelling and steering screw steam-vessels.* Dated May 12, 1862.

In carrying out these improvements for screw steam vessels, the patentee abandons the rudder as it is at present made and used, and substitutes what may be termed its skeleton, consisting of three sides or bars of an open rectangular frame, the top and bottom bars being united at eight angles to a vertical bar. The open side of the frame must be nearest the stern post, and the vertical bar farthest from it. The forward end of the bottom bar is pivoted into the projecting end of the keel, if there is one, or it may be pivoted into a bearing at the lower end of the stern post. The front or forward end of the top bar is turned upwards, and occupies the place and office of a rudder head, and is subjected in board to the control of the usual appliances for governing the helm or tiller, or to such other appliances as may be required, whereby the helm or tiller may be subjected to a right and left movement, the same as for a rudder. The rear end of the main propeller shaft must project only far enough through the stern of the vessel or through the dead wood or stern post, to be connected by a universal joint to the forward end of a short shaft, which will thereby be caused to rotate with it. The short shaft passes through the open frame, its rear end working in a bearing half way up the rear upright bar, and it carries the screw propeller, which revolves with it, within the opening of the frame; and as the frame can be turned to the right or left like a rudder, and as the universal joint at the front end of the short axis of the screw propeller will at the same time allow the axis and propeller to be turned along with it, the rotary action of the propeller will, owing to its thrust being then at an angle with the course of the vessel, quickly cause the vessel to take a new direction. Thus, with these arrangements, the putting of the helm to port or starboard will have the same effect in steering the vessel by the propeller frame as by the rudder, with the difference that the frame with the propeller will do it more effectively and speedily than the rudder, and will be found reliable in such cases as have lately been reported, and where the rudder was found wanting in effectiveness. *Patent completed.*

1425. W. N. HUTCHINSON. *An improvement in screw propelled ships.* Dated May 12, 1862.

This invention was described and illustrated at page 330 of the present volume of this journal. *Patent completed.*

1426. C. J. NEALE. *Improvements in apparatuses for measuring and registering corn and other grain.* Dated May 12, 1862

The patentee claims constructing apparatuses for measuring and registering corn and other grain with a drum or ring held in an outer ring or casing, and fixed on a shaft connected with registering wheels, all as described. *Patent completed.*

1427. H. ASHWORTH. *Improvements in machinery for opening and carding cotton and other fibrous substances.* Dated May 12, 1862.

Here the patentee makes use of a machine similar to a carding engine. The cotton, tares, or other fabrics or fibrous substances, are supplied to one or two pairs of feeding rollers, which are heavily weighted, and revolve very slowly; by these rollers, which are fluted or covered with needle points, they are delivered to a roller similar to the "lickerin," but covered with strong card teeth, and revolving at a great velocity, which deposits them on to the main cylinder, around which are placed working and stripping rollers or card flats of usual construction. *Patent completed.*

1428. J. L. WILSON. *Improvements in calendering woven fabrics, and in the apparatus employed for this purpose.* Dated May 12, 1862.

Here the inventor calenders, by means of rollers arranged to press and rub a part only of the fabric, leaving other parts plain or uncalendered, so as to produce a stripe on the fabric. *Patent abandoned.*

1429. A. B. FREELAND. *Improvements in the preparation or treatment of hops.* Dated May 12, 1862.

Here the patentee takes the hops, by preference, in the state in which they are usually packed into the pockets, and submits them to heavy pressure, and exposes them for some time to a moderate heat, whilst under pressure. He proceeds by preference as follows:—He employs a press having a rectangular trunk into which the hops are put, a metal plate being placed under, and another over them; the press is then set to work to compress the hops between the two plates, and when sufficient pressure has been applied, the plates are clamped together and removed from the press with the hops between them; in this state they are placed in a stove and exposed to a moderate heat, until the hops become set; they are then removed from the stove, allowed to cool, and unclamped. In this way a solid block of hops is obtained, which may be kept for a long time without any considerable loss of the aroma of the hops, and the hops in this form will occupy comparatively a small speed. He prefers to protect the block during transport, and whilst in store, by sewing it up in a wrapper of fabric. *Patent completed.*

1430. E. F. LANSKEY. *An improved mode of, and apparatus for, working railway carriage breaks.* Dated May 12, 1862.

Here the inventor proposes to utilize the power obtainable from the rotating axles or wheels of the carriages and engines, and applies the same to draw the brakes into contact with their respective wheels, when the speed of the train is required to be slackened. *Patent abandoned.*

1431. T. BUCKNEY. *Improvements in portable "tell-tale" timekeepers.* (A communication.) Dated May 12, 1862.

This invention comprises, among its chief features, 1, the construction and employment of portable timekeepers having no fixed dial and pointers, as in ordinary timekeepers, but in which a removeable paper disc, fixed upon and revolving with a plate actuated by a clock work, serves both to indicate the time to the watchman or other person, and to register the duties performed by such person. 2, The construction and use of portable tell-tale timekeepers, in which the impression of the various type fixed at the various localities are made upon the revolving paper dial by the agency of black or coloured transfer material. 3, The construction and employment of type boxes fixed at the various localities containing a fixed type for making the impressions upon the paper dial of the portable timekeepers, such timekeepers being for that purpose inserted into these boxes, which type boxes, when not used, are secured by a door or lid. 4, The arrangement of the fixed type in the various type boxes at different distances from the centre, and the formation of annular divisions upon the back of the paper dial, corresponding with the positions of such type, so that the impression of each separate type is made upon a different annular division on the paper dial, all as described. *Patent completed.*

1432. S. B. ARDREY and S. BECKETT. *Improvements in machinery or apparatus for manufacturing spindles, part of which apparatus is also applicable to grinding and polishing other articles.* Dated May 13, 1862.

Here the patentees take the spindles in their forged or black state, and heat them, and then place them in a machine or apparatus having a number of dies, which dies are pressed on different parts of the spindles by wedges acted upon by a lever, so as to set or straighten them perfectly, without any hammering, the lever being put in motion either by hand or power. 2, Each spindle, after it has been straightened, is centred and squared at one end, and placed in a machine or apparatus to be grooved in a self-acting manner, and instead of driving the spindle by a catch and driver, as at present, the patentees place the square end in a plate or chuck having a square hole to receive it, the plate or chuck being attached to the mandril of the headstock. The aforesaid machine is provided with centres and revolving stays for holding the spindles, and a pulley for giving it a revolving motion. The grindstone has a reverse motion to that of the spindle, and is guided longitudinally by a shaper corresponding with the desired shape of the spindle, there being a spring for the purpose of causing the flame and stone to follow the shape of the shaper, and also to adjust the revolving stays, so as to adapt them to the varied sizes of the spindle. It is evident that this apparatus can also be applied for grinding and polishing other articles. 3, They form in the interior of the wharve a number of shallow slots, so as to form a number of projections which yield to the exact size of the spindle, and enable the wharve to be pressed on to its place without endangering the truth of the spindle. The slotting of the wharves and pressing them on the spindles are both performed in an apparatus consisting of a press worked by a screw, from which the nut can be detached at any part, so as to allow the screw of the press to rise to its original position without loss of time. *Patent completed.*

1433. J. H. JOHNSON. *Improvements in the modes of carrying out submerged and other engineering works.* (A communication.) Dated May 13, 1862.

It is by this invention proposed to use a casing of any suitable impermeable and flexible material, inside of which the operations necessary for the carrying out of the works are performed, so that the workmen will always be enclosed in a water-tight and weather proof chamber. *Patent abandoned.*

1434. J. D. CAVILLET and J. P. F. GANDON. *Improvements in paddle-wheels, applied either for propelling steamboats or as prime movers.* Dated May 13, 1862.

This consists in a peculiar arrangement and combination of the paddles or pallets of water-wheels used either for propelling steamboats or as prime movers, which paddles are hinged on horizontal shafts, properly disposed around the circular plate or frame of the said wheels, so that these paddles move freely on their shafts as the wheel revolves. The hinging point being at about the third part of the length of the paddles, the longest or heaviest side falls freely downwards when out of the water, and when the fluid presses on them, the longest arm of the said paddles bears against stopping rods or bolts fastened in the wheel on each side of the paddles, so as to stop its hinge motion on either side in the most advantageous position, either to work or slide through the water as the wheel revolves, allowing them to

take a radial position, which is maintained as long as they work, and is modified before getting out of the water, so as to avoid their raising any of the fluid, as is the case with common paddle wheels. *Patent abandoned.*

1435. P. M. LOPEZ. *Improvements in apparatus for sowing wheat or other grain or seeds.* Dated May 13, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1436. J. B. SARDEY. *Improvements in the construction of ships of war and other vessels.* Dated May 13, 1862.

In order to obviate the difficulties experienced in constructing iron-clad steam ships, carrying powerful machinery and formidable armament, which greatly increases their draft of water, three or more keels may be used, according to the size of the vessel, and two or more stern posts, having between each a central keel and run inclining from the after body of the ship, and terminating at the main transom. By this arrangement a very flat bottom, with easy bilges to the hull and good sailing lines, can be obtained, with a greater width of beam than usual, extending very far aft, and the stern extending in one body above and abaft the rudders and screws to protect them, and to be constructed for the purpose of a battering ram if required. The invention relates, 2, To the use of a battering ram built on one or both ends of the said vessel, for the purpose of acting against other vessels or structures. *Patent abandoned.*

1437. W. E. NEWTON. *Improvements in coffee-pots and boilers for culinary purposes, parts of which improvements are also applicable for generating steam.* (A communication.) Dated May 13, 1862.

This consists—1, In combining a convolute or coiled tube with a boiler, central tubes, and perforated food holder or receptacle, so that, when heat is applied to the apparatus, and the water commences to be heated, a circulation or current will be formed within the boiler, and the water very soon heated and boiled, while the substance or material to be boiled will be disposed in the most advantageous manner in the current of water, to form the cooking or extracting process. 2, In using, in connection with the boiler, a coiled tube and food holder, or receptacle, aforesaid, one or more supplemental chambers or vessels placed under and over the other, and communicating with each other, and the boiler by a tube or tubes, constructed and arranged to favour the ascent of steam or heated air, with the supplemental chambers for warming or cooking articles of food, and, at the same time, serve as a means to keep the cover or lid of the receptacle or boiler in proper position. *Patent abandoned.*

1438. A. WORMULL. *Improvements in trepanning instruments.* Dated May 13, 1862.

This consists in constructing these instruments so that the cutting tool may have the required rotary motion communicated to it by means of some convenient mechanical arrangement of gearing, instead of this motion being given by the twist of the operator as heretofore. The invention is not described apart from the drawings. *Patent completed.*

1439. G. BLAKE. *Improvements in apparatus for warming apartments.* Dated May 13, 1862.

This relates to a peculiar construction and arrangement of a warm-air stove, and consists in causing such stove to be heated by a fire placed externally thereto, in lieu of the fire being situate inside thereof, the air being heated as it passes through the interior of the stove. In order to present as large a heating surface to the air as possible, it is proposed to apply a number of surface-plates, or partitions, inside the stove, the air passing through the intervening spaces between such plates or partitions. *Patent completed.*

1440. J. H. JOHNSON. *Improvements in the purification of colza, rape, and other oils.* (A communication.) Dated May 13, 1862.

Here it is proposed to subject the oil under treatment to violent agitation, in a suitable vessel, with a view to the mixing of air or gas therewith, sulphuric acid being poured gently into the oil during such aërating process, in lieu of using beaters, agitators, or other mechanical means, for mixing the air with the oil; a perforated pipe may be placed near the bottom of the vessel, and air or gas formed therein, such air or gas penetrating the oil in innumerable small streams or jets. The scum which rises to the surface is then removed, and the agitating process is repeated, the fresh scum being removed between each agitation. At the last agitation, a small quantity of water is added, so that the oil becomes thoroughly mixed with air and water. The sulpho-fatty acids are then destroyed, and the sulphuric acid is drawn off, and the impurities removed by washing the oil in hot water or by steam. The oil is now dried over a fire, or by steam heat, and is afterwards cooled by any suitable refrigerator, when it will be found to be perfectly pure and ready for the market. *Patent completed.*

1441. R. A. BOYD. *Improvements in the manufacture of bacon.* Dated May 13, 1862.

Here the inventor prepares the carcases of pigs for making them into bacon, by first removing the bristles, by passing them through heated water or steam, and afterwards scorching the skins by the action of flame or heat, in a stove or otherwise. *Patent abandoned.*

1442. J. SWENWRIGHT. *Improvements in the manufacture of polished plate-glass.* Dated May 13, 1862.

This consists in using for rolling out the glass a table which is not smooth, but has shallow ribs on its face; or a roller which, in place of being smooth, has similar projections on its surface. These projections may be either simple bands round the roller, or in the form of a spiral from end to end. These projections indent the glass, and it results that the sheet, on cooling, has a comparatively even face. The annealing, grinding, and polishing, is afterwards conducted in the ordinary way. *Patent abandoned.*

1443. W. CLARK. *Improvements in apparatus for generating motion in fluids, applicable for raising and forcing water, propelling and otherwise, in the distribution of motive power.* (A communication). Dated May 13, 1862.

This relates to hydraulic apparatus, in which steam is received in a fluid chamber, and by it separated from the water, its condensation being also prevented, while at the same time it is reduced for transmitting movement to the liquid, by utilizing the expansion of the steam for raising columns of water in motion. *Patent completed.*

1444. W. HARTICAN. *Improvements in fire-escape apparatus.* Dated May 13, 1862.

This consists, 1, Of an iron framing, which fixes on the lower part of the window. This framing is formed of two cramp-like parts, between which are stretchers or bars holding them in position. These cramps embrace the substance of the wall at the lower part of the window, and have on the inside projections to take under the beading or projections inside the window. These projections may be adjustible, and fixed by screws or otherwise. On the outside ends of the cramps are screws that take under the sill, and by turning which the whole framing is fixed rigidly in position. To the framing or outside ends of the cramps, are fixed two ropes, of sufficient length, so that, hanging down, they may properly reach the ground, and extend to the opposite side of a street. Between these ropes is fitted a canvass bag, suitable for persons getting into. It runs on the two ropes by thimbles fixed thereto, the bag being roped, and the thimbles being distributed throughout its length on each side. Two small blocks or pullies are appended to the iron framework before named, over which are rove two small ropes or lines, the one end of each rope being fastened to the bag, and the other leading down to the ground. By these lines the bag can be hauled up and down the standing, or inclined ropes, and persons so lowered from the window. *Patent abandoned.*

1445. R. A. BROOMAN. *An improved means or apparatus for shunting trains.* (A communication.) Dated May 13, 1862.

The object of this invention is to enable a train to be shunted or moved from one line of rails to another, without the aid of an attendant. The invention consists in fitting to the front or side of locomotives, tenders, or carriages in front of a train, a projecting rod or rods, which comes or come in contact with a weighted lever or levers on the rail, and which, through the medium of rods or chains, draw the points together, and cause the course of the train to be diverted. *Patent abandoned.*

1446. R. A. BROOMAN. *Improvements in louvre blinds or shutters.* (A communication.) Dated May 13, 1862.

This invention consists in forming the blinds entirely of iron, or with wooden frames and iron slots, as hereafter described. The frames are formed of iron uprights united at top, bottom, and about the centre, by cross bars; or the frames may be made of wood, lined with metal. The slots carry a pivot at each end, which pivots are received in holes made for their reception in the uprights—connecting pieces unite all the slots to an upright bar at the back of the blind. This bar is furnished with a handle, and has notches formed in it; the handle is for the purpose of altering the inclination of the slots, and the notches receive a pawl or rod for the purpose of maintaining the slots at the angle desired. In some cases the slots are fixtures, being connected by screws at their ends. The fastening for opening and closing the blinds consists of two bars which carry at their inner ends, at or about the centre, a link connected by a pin to a cross bar in the shaft of a handle. By turning the cross bar in one direction the bars are drawn inwards and released from their lodgments in the window sills at top and bottom, while in turning the cross bar in the contrary direction they are thrust outwards and are made to engage in their lodgments and thus lock the blind. *Patent abandoned.*

1447. W. SOUTHWOOD. *Improvements in machinery for manufacturing nails from either hot or cold bars of iron or other metal.* Dated May 13, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1448. R. M. LATHAM. *Improvements in steering apparatus.* (A communication.) Dated May 13, 1862.

This invention is carried into effect as follows:—To the steering wheel is adjusted a spindle supported upon proper bearings, upon which spindle is a vertical pinion gearing into a horizontal wheel attached to an upright shaft to be secured to the deck, and to this shaft the patentee attaches a wheel which gears into a quadrant; this quadrant is secured to a proper attachment, the latter embracing the rudder head, which attachment and quadrant he prefers should be in one casting. The lower part of the attachment which encircles the rudder head fits into a ring or socket, which has a flange intended to be secured to the deck. The ring and attachment where they come into contact should be placed to prevent friction. The wheel which gears with the quadrant should be of such depth, that it will allow the rudder to rise moderately, without any danger of throwing the apparatus out of gear. *Patent completed.*

1449. M. HENRY. *An improvement in, or addition to, gloves.* (A communication.) Dated May 13, 1862.

Here the glove is formed with a band or strip intended to lie around or near the wrist, and manufactured of soft kid. The further edge of the band or strip is angular or curved, in a direction away from or outward of the glove; when the glove is on the hand, the angle, or the outermost point of the curve, generally lies towards or over the centre of the wrist or cuff, or farthest from the glove. *Patent abandoned.*

1450. C. T. PORTER. *Improvements in steam indicators.* (A communication.) Dated May 14, 1862.

This consists in the use of a lever or its equivalent, so connected with the pencil and the piston as to give to the pencil a range of motion greater than that of the piston, in combination with a system of levers, or an equivalent therefor, so as to arrange the pencil point to travel in a straight line, substantially as described. *Patent completed.*

1451. H. C. R. JOUBERT. *Raising a music chair, stool, or seat, which entirely supersedes the original screw now in use.* Dated May 14, 1862.

This consists of a music chair, stool, or seat, rising to any height required, by vertical saw teeth racks fixed to the seat, and having in the lower frame a catch to each rack; by pressing a knob the catches open, and thereby allow the person to adjust the seat to any height required. *Patent abandoned.*

1452. F. TOLHAUSEN. *Improvements in the manufacture of velvets.* (A communication.) Dated May 14, 1862.

The loom the inventor uses for double-faced velvets resembles that now in use for the said fabric, but he arranges it so that, instead of there being only two ground warps or pieces one above the other, there are three one above the other. He uses two pile warps and two knives. In this manner he obtains three textures of fabrics one above the other, and, the pile being cut by the two knives, the result will be a double-faced velvet fabric in the middle, and one single-faced velvet above and beneath. Three shuttles are used, instead of two, and in order to overcome the difficulty that would have to be experienced in picking these shuttles simultaneously, he provides the two ground warp heddles, or healds, with three eyes each, and the pile heddle with two eyes, a proper shed being thus ensured for the easy passage of the shuttles. *Patent abandoned.*

1453. R. A. BROOMAN. *An improved method and apparatus for the production of photographic and stereoscopic portraits and pictures.* (A communication.) Dated May 14, 1862.

This invention consists—1, In the construction and employment of instruments containing lenses capable of producing portraits or pictures distorted in length, breadth, and obliquity, whether from the person or object, or from engravings, prints, or other representations. 2, In the production of a new style of photographic portrait, distorted in length, breadth, and obliquity, possessing all the clearness of an ordinary portrait. 3, In the application of these portraits to the stereoscope. 4, In uniting and combining a pair of distorted portraits, according to the plan adopted for stereoscopic pictures, reciprocally taken at the desired angles, all as described. *Patent completed.*

1454. J. W. GIRDLESTONE. *Improvements in projectiles.* Dated May 14, 1862.

Here the inventor encases the shot or projectile for rifled ordnance or firearms in a jacket of wood or papier maché, so that the jacket fits the bore, and being urged against the wedge-shaped rear of the ball, which is at first not quite home in the jacket, by the explosion is expanded into the grooves of the bore. The jacket receives a rotary motion from the grooves, and imparts the motion to the projectile by means of a projection on the jacket and recess in the projectile, or *vice versa*. The jacket falls off or comes to pieces after it has left the gun, this operation being sometimes facilitated by longitudinal saw cuts, extending from the front towards the rear. The jacket may have annular or cellular recesses, so as to reduce the friction and diminish the weight, and to strengthen the rear a plate of metal or other resisting material; and where shot for rifled or smooth advance is to be used against armour plates, the head or striking part of the projectile may be made slightly concave to improve its penetrating powers. *Patent abandoned.*

1455. H. DEACON. *Improvements in the manufacture and production of certain colours and in the apparatus employed therein.* Dated May 14, 1862.

The patentee claims, 1, The general system or mode of manufacturing or producing colours, and the construction, arrangement, and combination of apparatus used therein, as described. 2, The application and use to, and in the manufacture or production of, the said colours of retorts, ovens, or furnaces, so constructed as to admit of their contents being inspected, stirred, or otherwise manipulated without injury from the admission of atmospheric air. 3, The application and use to, and in the primary heating process in, the manufacturing or production of, the said colour of close or blind furnaces, or ovens, similar to those used in the manufacture of alkali for roasting salt cake or sulphate of soda. 4, The washing of the said colours in what are known as circulating vats or tanks, similar in principle to those employed in the manufacture of alkali for the lixiviation of black ash. *Patent completed.*

1456. A. SMITH. *Improvements in balances for weighing letters and other documents.* Dated May 14, 1862.

These balances are arranged for indicating the weight of articles suspended thereto without the aid of loose weights, and are constructed upon a principle which is somewhat analagous to that of the common steel-yard balance. Under the improved form of this invention, however, the fulcrum or points of support upon which the bar is balanced is moveable, and the bar or lever is graduated from its inferior to its superior end, the former being enlarged to act as a counterpoise, and the latter being fitted with a looped or other holder or scale for receiving the letter or other article to be weighed. The moving fulcrum is traversed along the bar to the centre of gravity, when the graduation thread indicates the weight. *Patent completed.*

1457. E. WHITTAKER and J. CLARE. *Improvements in machinery or apparatus for preparing cotton or other fibrous materials to be spun.* Dated May 14, 1862.

In the machines commonly known as the opener, or scutcher and beater, the patentee uses revolving rollers instead of the ordinary fixed grate bars or grid, through which the dirt or refuse passes. The said rollers are plain, grooved, or notched, or have a screw thread formed in them, and are placed either in a longitudinal, transverse, or diagonal position, and have, when required, motion given to them in any convenient manner, either by hand or power. *Patent completed.*

1458. H. G. DELVIGNE. *Improvements in fire-arms.* Dated May 14, 1862.

In this improved construction of pistol the inventor dispenses with the usual trigger, and substitutes a small rod inserted in a passage or channel in a metal bracket, which occupies the position of the ordinary trigger guard. By pressing against the front end of the rod with the forefinger, the rod is made to slide in the passage, and its hind end is thereby caused to act on the lock and discharge the

pistol. On the finger being removed, the rod is returned to its first position by a coiled spring. The second part of the invention relates to breech-loading arms for discharging several projectiles simultaneously through a number of barrels combined so as to form one, or through bores or channels in the same barrel. The barrels terminate in a breech-piece to which the stock is connected by a short screw, through the centre whereof is formed a touchhole, which, when the movable charge cylinder has been inserted in its place, communicates with the central chamber of that cylinder. *Patent abandoned.*

1459. J. SMITH. *Improvements in thrashing machines.* Dated May 14, 1862.

The patentee claims, 1, The employing of a current of artificially heated air obtained from the steam engine which drives the thrashing machine, or other source for winnowing the grain as it passes over the riddles and falls from riddle to riddle. 2, Subjecting the grain, as it passes from one part of the machine to another, to a current of artificially heated air continuously, or at various stages of its passages. 3, Causing the grain, as it passes from one part of a thrashing machine to another, to pass through a passage surrounded by a steam jacket heated by steam pipes or cases connected by shuttle pipes with the boiler of the engine which drives the thrashing machine. *Patent completed.*

1460. J. C. BRANT. *Improvements in the construction of armour plated ships, and in cements or compositions, or uniting iron to iron, and for uniting other substances, which compositions may also be used for caulking and for coating ships' bottoms.* Dated May 14, 1862.

In manufacturing cement according to this invention the inventor combines manganese or magnetic oxide of iron with oil of turpentine, or any other essential oil, and adds to it Swedish or other pitch and gutta-percha—resins and resinous gums, may also be added. The improvements in armour coated ships consist in preventing water from getting between the armour plates and the outer skin of the vessel by uniting the back of the armour plates to the skin by the cement above described. The invention also consists in placing a layer of cork, or a layer of lead, or a layer of cork together with a layer of lead, between the skin of the vessel and the back of the armour plates. *Patent abandoned.*

1461. A. NICOLE. *Improvements in stop watches and timekeepers, and in instruments for measuring accurately short intervals of time.* Dated May 14, 1862.

This invention consists in so arranging the above, that by pressure on a detent, an extra second's hand may be caused to start from a zero point on the dial, and may continue to run, marking seconds and fractions thereof, until the same detent is again pressed on, when the extra second's hand is stopped, and so remains until the detent is a third time pressed on, when it flies back to the zero point from which it started. The patentee also, according to this invention, mounts the extra second's hand, having the power of starting, stopping, and flying back to zero, as above mentioned, on a separate axis from that which carries the ordinary second's hands, and at a distance therefrom, by which means he is enabled conveniently to bring the extra second's hand to the centre of the watch, whilst at the same time the extra second's hand and its mechanism, when out of action, can be entirely separated from the moving parts of the watch, thus avoiding an increase of friction which would otherwise result.

1462. J. FLETCHER and J. W. FULLER. *Improvements in machinery for rolling, bending, and planing tools.* Dated May 15, 1862.

The first part of this invention consists in the application of hydraulic pressure for forcing up and drawing back the squeezing or nipping rolls of machinery for rolling tyres, hoops, and other circles of steel, iron, or other metal. The second part of the invention consists of an improved combination of machinery for bending armour or other strong metal plates. The third part of the invention consists in the application of friction cones or other friction apparatus for driving planing machines. *Patent abandoned.*

1463. T. H. C. MESURIER. *Improvements in raising sunken vessels and other heavy bodies.* Dated May 15, 1862.

This invention consists in the employment for that purpose of one or more cylindrical or other shaped closed vessels, divided internally so as to leave an air space or chamber at each end. The central portion of these vessels is perforated to allow water to enter freely therein when submerged, and is provided with a flexible or other air-pipe which serves the purpose of allowing the escape of the air from the water space of the cylinders whilst they are filling, and of allowing air to be forced therein in order to expel the water when the cylinders have been properly secured to the sunken vessel or other body. These cylinders are guided down to their proper positions by cords which are secured at their lower ends to iron balls attached to lengths of chain secured to the vessel, whilst the upper ends of the cords are supported by buoys or floats. Tubular passages are made transversely in a vertical direction through the cylinders, through which passages the cords are passed, so that the cylinders are guided to the sunken vessel as they descend. The tubes are made large enough to allow the balls to pass, but so soon as they have passed through, suitable hinged catches on the upper ends of the tubes close and prevent the cylinder from rising again, except with the balls and chains attached to the vessel, the attachment of the cylinders being thus self-acting. The air chambers at each end of the cylinder serve to check the rapid descent of the cylinders, and tend to keep the cylinders horizontal. Suitable bent pipes are fitted to the lower side of the cylinder opening into each end of the water chambers, for the purpose of enabling the whole of the water to be forced out in case the cylinder should be attached to the vessel in an inclined position. *Patent abandoned.*

1464. G. H. SANBORN. *Improvements in machinery for spinning.* (A communication.) Dated May 15, 1862.

The object of these improvements is to increase the rapidity with which yarns have hitherto been twisted by machinery, to decrease the required power, to arrange the different parts of the spinning machines in the least possible space, and to easily regulate the number of twists in a given measure of yarn, for the purpose of more perfectly adapting it to various purposes, and for the manufacture of different fabrics. The chief peculiarity of the invention consists in the employment of two or more reels or "flyers" arranged in succession one within another, the inner flyer or flyers being so geared as to revolve in the same or opposite directions to the outside one, and at the same or different rates of speed from the said outside flyer, as may be desired, for the purpose of obtaining different degrees of twist in the yarn. *Patent abandoned.*

1465. R. WALSHAM and J. WALSHAM. *A new or improved sleeve tie or fastener.* Dated May 15, 1862.

To each end of a piece of elastic webbing of rather more than an inch long the inventors attach a metallic hook, one of the said hooks having a loop fixed to it, into which loop the other hook may be inserted at pleasure. In using this sleeve tie or fastener, the elastic webbing is passed under the sleeve, and the hook on one end of the webbing being made to engage with the loop on the other hook, the sleeve is gathered up and secured on or near the shoulder. On removing the hook from the loop, the sleeve is loosed, and the sleeve tie or fastener may be removed. *Patent abandoned.*

1466. J. P. JOUVEN. *An improved process for preserving iron-plated and other vessels and metallic articles from oxidation, and preventing ships' bottoms from fouling.* Dated May 15, 1862.

The patentee claims, 1, The applying, and the mode of applying, to the interior surface of iron and iron-plated ships, zinc sheets, either alone or together with metallic paint or felt, sprinkled with metallic zinc powder, to preserve iron-plated and other ships from the destructive action of sea-water, as described. 2, The production of a poisonous compound, and its application to the bottoms of iron and iron-plated ships, and to wood used to construct dikes, embankments, docks, and for naval and other similar constructions, in order to prevent for the former the deposit of barnacles and seaweeds, and to protect the latter from injury from teredos, as described. 3, The application to parts of iron ships, and to iron articles, of a paint having pulverized metallic zinc for base, applicable as a substitute for red lead paint, as described. 4, The application of sheets of zinc, or metallic zinc paint, to the exterior of sheet iron tanks, marine boilers, steam engines, and other like articles, and the application of bands of zinc to parts of cables and chains, as described. 5. The application to the hulls of copper-sheathed wooden vessels of protecting paint, which, for economy, may be made with cast iron, or iron powder, instead of zinc powder, as described. *Patent completed.*

1467. J. DICKER. *Improvements in apparatus for the delivery of bags or parcels from railway trains in motion.* Dated May 15, 1862.

This invention is carried into effect as follows:—To the near side of the railway carriage is attached one or more projecting arms, from which the bag or parcel to be delivered is suspended. When the bag or parcels have been delivered, these projecting arms are drawn up close against the side of the carriage, by means of a counterbalance weight inside. At the corresponding side of the railway there is erected an upright receiving standard and framework, furnished with diverging lines, to disengage the bag or parcel from the projecting arm; as soon as the bag or parcel leaves the projecting arm it is received upon an inclined platform, which conducts it down behind the standard clear of the rails. Any required number of bags or parcels can in this way be delivered at a station from railway trains while they are in motion. *Patent completed.*

1468. W. SISSONS. *Improvements in machinery for driving piles by means of steam hammers.* Dated May 15, 1862.

This invention consists of an improved description of catch for lifting and releasing the hammer, to allow it to fall upon and drive the pile into the ground. And, also, in the application thereof, in conjunction with the improved arrangement of steam power, to the hand piling machine, and, likewise, the combination of a steam-engine, with framing, moveable platform, chain and catch, for the purpose of pile driving. The invention cannot be described in detail without reference to the drawings. *Patent completed.*

1469. G. H. BIRKBECK. *Improvements in apparatus for consuming smoke.* (A communication). Dated May 15, 1862.

For the purpose of this invention, the grate or fire-bar surface is formed with a hollow or recess, by preference of a curved or concave form; but it may be of conical or pyramidal, or other suitable shape, if desired, commencing from and in the "dead plate," and inclined from the front upwards, towards the back of the furnace, or fire-place. This hollow channel or passage is prolonged outwards, from the front of the furnace, forming a conduit or conductor, and it is furnished with a receptacle, made of sheet iron, which receives and retains the fuel till required to supply the fire, the fuel being fed or pushed forward therein, and fed into the furnace by means of a piston, actuated by a screw or otherwise. The unignited fuel, as it is forced forward into the furnace, is caused to pass underneath the ignited or incandescent fuel, and as the smoke and gases are generated, they become ignited, and are consumed, the fuel, by the hollow or recess being conical, or inclined, is gradually distributed over the surface of the fire-bars. In large furnaces, two or more feeding channels or passages, and apparatus to force and conduct the fuel into the furnace, may be employed if required. *Patent completed.*

1470. J. STONE. *Improvements in Downton's ships' bilge pumps and fire-engines.* Dated May 15, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1471. J. WRIGHT. *An improved rotative travelling crane.* (A communication). Dated May 15, 1862.

Provisional protection has not been allowed for this invention.

1472. J. WRIGHT. *Improvements in machinery for digging, excavating, and removing earth, gravel, and such like substances.* (A communication.) Dated May 15, 1862.

This invention consists in an improved form of excavator, to be worked by steam or air, and which is capable of being moved on rails near the ground to be excavated, and which removes the dirt, stones, gravel, and such matters to any distance that may be required. The patentee places on a suitable frame, and mounted on wheels, a boiler and engine. This engine drives a toothed wheel, which gives motion to another similar wheel, on whose axle is a square frame, over which passes an endless chain of links, carrying a series of buckets or scoops; each bucket or scoop is preceded by a coulter or knife, for penetrating and loosening the earth or soil, which is then scraped up by the scoop or bucket. The endless chain carrying these buckets is kept at the required tension by a pole, which can be raised or lowered by means of cords and pulleys on the frame of the machine. On the axle of the first-mentioned toothed wheel is an endless band, passing round and kept tight by a tension pole or rod, similar to the one before named; this pole may be of any length, and can be raised or lowered as wished. The action is as follows:—Motion being given to the toothed wheel carrying the square on which is the endless chain of buckets, these are lowered to the required depth, and sink by their own weight into the ground; these buckets are open on the side next the chain, and, when in action, are kept close against it; but when they come over the pulley, they turn over by their own weight, and discharge their contents on the endless table before mentioned, which removes it into a truck. This machine can be moved in any direction on rails, and when placed on a boat it serves as a dredging machine, with the advantage of raising the mud without disturbing the bottom. *Patent completed.*

1473. C. ATTWOOD. *Improvements in the production or manufacture of steel and iron of a steely quality.* Dated May 15, 1862.

This invention essentially consists in the production of steel and of iron of a quality approximate to steel, which may be called steely iron, simply by bringing into a state of liquefaction by means of heat a mixture of malleable iron of such kinds as in themselves are capable of producing good serviceable steel and steely iron, and of a certain kind or kinds of non-malleable or crude cast iron, such, for instance, as are usually called spiegal risen, which are also by their own nature capable of being made into good and serviceable steel in certain proportions to each other (as specified), by which mixture and liquefaction of those materials hard steel, or soft steel, or steely iron, are respectively produced, according to the different proportions in which such two several materials or ingredients may be severally employed, such proportions also requiring to be varied according to the difference in their quality in respect of the greater quantity of carbon contained in each, and to their greater or less tendency in consequence thereof, to make such steel or steely iron of harder or softer quality. *Patent completed.*

1474. C. TRESS. *Improvements in the manufacture of hats, helmets, bonnets, or caps.* Dated May 15, 1862.

This invention consists in a method of constructing the above-named articles whereby currents of air may readily pass from the exterior to the interior thereof, an air chamber, cells, or cavities being formed therein above and surrounding the head of the wearer, in order to ventilate and keep the head or interior cool in hot weather, or tropical climates, and where else required. *Patent completed.*

1475. J. BAGGS and W. SIMPSON. *Improvements in treating straw, Spanish grass, and other vegetable fibres in preparing a bleaching agent for vegetable fibres, and in recovering and treating an alkali resulting from the treatment of the said fibres, and in apparatuses employed therein.* Dated May 15, 1862.

This invention consists, 1, in removing the silex from straw, Spanish grass, and other vegetable fibres, by means of hydrofluoric acid, either in a liquid form, or in the form of gas. The patentees construct an apparatus or vessel in which the fibres are subjected to the action of the gas as follows:—They take a cylinder formed with screw vanes or blades on the interior thereof, and carry a perforated pipe through the centre; this pipe is in communication at one end with the gas supply, and also with an air pipe, through which air is forced by a fan or otherwise. The straw or other fibre is fed in by a tilting rake or other like contrivance at one end of the cylinder, which, being caused to revolve, carries the fibres gradually along, and finally out at the opposite end. 2, In the partial recovery of the alkali from the liquor in which the straw or other fibre has been boiled by means of steam or hot water. 3, In the distillation of the residuum after boiling and evaporation in a close retort, whereby they obtain a gas fit for illuminating purposes. 4, In manufacturing chlorine for bleaching the said fibres and others, as follows: They take two separate vessels, one of which (say in the form of a retort) contains substances from which muriatic acid gas is generated, while the other contains the materials which decompose the muriatic acid and give off chlorine. They prefer to mount this second vessel upon trunnions. The gas is led from the first into the second vessel; and the chlorine evolved in the second vessel is led into a third vessel containing water, or water and lime, or other base and an agitator. The chlorine is absorbed, and a bleaching liquid obtained. *Patent completed.*

1476. C. GIRARDET. *An improved construction of buckle.* Dated May 15, 1862

Instead of forming this buckle with a tongue hinged to the buckle frame, the inventor uses the ends of the frame as parallel guides to receive an open sliding frame, the nip of which serves to hold the free end of the strap in position. One bar of the sliding frame is pierced to allow of the ordinary prongs (which are carried by one of the side bars of the buckle frame) projecting therein, and offering no obstruction to the sliding of the inner frame on its guides. The free end of the strap intended to be secured is passed

through the sliding frame, and that frame is then moved forward until the fixed prongs enter the fabric of which the strap or band is composed. The strap will thus be held fast, and any drag put upon it will tend to increase the security of the buckle. *Patent abandoned.*

1477. A. WATNEY. *Improvements in constructing ships, vessels, and other structures intended to resist shot.* Dated May 16, 1862.

According to this invention, the patentee forms the side of a ship or vessel intended to resist shot in the following manner:—He builds up the structure of a series of iron (or it may be steel) plates, which may be of any convenient length and thickness; it is preferred, however, that the latter should not be great. These plates he lays one on the other, so that their edges only are exposed, and he annexes each plate by means of rivets to the plates in contact with it on either side. One half of the rivets which pass through each plate, are for the purpose of connecting it to the plates on one side, and the remainder to those on the other side of it. Each plate is prepared by punching a number of rivet holes through it, and these holes are countersunk, one half on one side of the plate, and the other half on the other. The holes in all the plates are accurately placed, so that they may correspond the one with the other. Each plate, before it is attached to the portion of the work already completed, has one half of the holes in it filled by rivets placed through them; the heads of these rivets all lie in the countersunk holes on one side of the plate, and the ends of the rivets project out from the plate on the other side. The plate with the rivets in it is then applied to the already finished portion of the work, the side from which the ends of the rivets project being outwards. From the side of the already finished work, the ends of rivets project, and these, when an additional plate is applied, pass through the previously unoccupied holes in the plates, and the plate is then secured by clenching these ends over the plate. The ends of the rivets placed through the plate previous to its application to the work, then project from it to receive other plates in a similar manner. The plates are arranged so as to break joint the one with the other. *Patent completed.*

1478. P. M. PARSONS. *Improvements in ordnance and other fire-arms, and in tools for rifling the same.* Dated May 16, 1862.

In carrying out one portion of this invention, the inventor forms the main portion of the gun of cast iron, but instead of casting it solid, or with a solid breech, as usual, he casts it with the bore right through; and he employs a hollow pipe encased in loam, or other suitable substance, to form the core, through which a stream of water is made to flow, while the gun is being cast, and during the time it is cooling. He then bores out a conical recess at the breech end of the gun, larger in diameter than the intended finished size of the bore, but extending only a portion of its length, and he fits into the recess a tube of wrought iron, steel, homogeneous metal, or other suitable material, accurately turned to the shape and size of the conical recess, which forces in, and secures by a breech plug screwed into the breech of the gun, in the case of muzzle loading guns, or by a nut or hollow screw in the case of breech loaders. The tube may be in one piece of metal, or built up of several, either by fitting two or more rings together, or by shrinking or forcing one or more tubes or rings on to an inner tube or tubes. He also applies the conical tube in the manner hereinbefore described to guns cast solid, or with an ordinary or solid metal core, as well as to guns already made for the purpose of strengthening them, and, in some cases, he applies the conical tube in combination with a tube of wrought iron, steel, homogeneous metal, or other suitable material with which the gun is lined throughout the whole length of the bore. *Patent abandoned.*

1479. J. RAILTON and T. RAILTON. *Improvements in warping machines.* Dated May 16, 1862.

The object of these improvements is to stop the warping machine instantly when one of the warp threads break. In order to accomplish this, the inventors apply the following self-acting apparatus to the warping machine:—Each warp thread is taken over a balanced lever, and these levers are hinged to a cross shaft, and they are guided by the dents of two open reeds; these parts are mounted on a vibrating frame, to which a link connected to the usual spring starting lever is pointed; under the weighted end of the balanced levers a rocking bar is moved to and fro by the warp beam or other convenient part of the machine. When the warp threads are all passing forward to the warp beam, the balanced levers are held clear of the rocking bar, but the moment a thread breaks. the balanced lever over which it was passing, drops, and the rocking bar coming in contact with it moves the vibrating frame, thereby liberating the spring starting lever from its retaining catch, and moving the driving strap from the fast to the loose pulley. *Patent abandoned.*

1480. G. HASELTINE. *Improvements in churns.* (A communication.) Dated May 16, 1862.

This invention relates to a novel construction of the dasher or plunger, and to a peculiar mode of operating the same. The body of the churn is made of any desirable material, form, and size. The dasher is constructed of wood of any form suited to the body of the churn in which it is to be used. It consists of an upright bar or standard, attached at its lower end to a main horizontal bar, to each end of which a transverse horizontal bar is fixed at right angles to the said main bar. On the under and inner sides of the transverse bars each side of the main bar shoulders are cut. These shoulders receive and arrest the upward movement of the wings or dashers hereinafter described. These wings or dashers are perforated to admit the passage of the milk or cream, and are attached by means of projections formed on the ends and at the sides next the main bar, which extends into holes bored in the transverse bars. These projections keep the dasher boards in position, and perform the office of hinges, allowing the dasher boards or wings to swing down as the dasher is raised up, until they are arrested by a bevelled block at an inclination of about 45°. This block is fixed to the main bar, the bevelled ends extending beyond the said bar, and over the dasher boards. The dasher is operated by means of a lever or handle attached to, and resting upon, the upright bar or standard. The end opposite to that at which the power is applied is fixed to a post outside the body of the churn, the lower end of the said post resting on a cleat fastened near the bottom of the said body, and diverging therefrom, being kept firm in its position by means of a brace running out from the churn. *Patent completed.*

1481. R. FENNER. *Improved machinery for folding envelopes.* Dated May 16, 1862.

In carrying out this invention the inventor places separate letters or figures made of iron, steel, brass, or other suitable metal, and forming the pattern to be embossed in due order upon a surface of iron or other sufficiently hard and strong material, and fills it in with wax or other similar plastic substance. He then lays the metal plate to be embossed upon these letters or figures, covering the surface not coming in contact with the characters with vulcanized india-rubber or other suitable material, and by the application of sufficient pressure produces a copy of the pattern in embossed or raised letters or figures. *Patent abandoned.*

1482. R. LAMING. *Improvements in constructing and using electric telegraphs.* Dated May 16, 1862.

The patentee claims as his invention, with respect to the electric telegraph generally, the adjustments of its parts to one another, as described, and also using either or both ends of a telegraph with its parts so adjusted in the way specified, or with such modifications as may embody his invention; but he does not claim the simple application of the opposite poles of two batteries at the two ends of a line, when unaccompanied with the adjustments to the wire of the voltaic elements and of the coils of instruments, opposite poles having already been so applied, though for a different purpose. And, with respect to marine electric telegraphs in particular, he claims the constructing and using of subaqueous telegraph cables with conductors immediately surrounded by insulators of dried organic materials in a fibrous condition, saturated with insulating cements. Also constructing and using subaqueous telegraph cables in which the insulation and the tensile strength are conferred, either wholly or in part, by dry organic materials used in a fibrous condition. Also the application and use of tubes and caoutchouc and of lead, and of servings of vulcanized caoutchouc, and of other coverings that are sufficiently impervious to water for keeping dry insulators of subaqueous telegraph cables composed of dried hemp and insulating cements, and that depend for their efficiency upon an artificial dessication, which perhaps they might not otherwise so perfectly maintain. *Patent abandoned.*

1483. C. BINKS. *Improved method of, and apparatus for, treating linseed and other oils and fats.* Dated May 16, 1862.

We cannot here devote space to the voluminous details of this invention. *Patent abandoned.*

1484. A. A. LAMIABLE. *Improvements in cementing cast and wrought-iron, to obtain cast steel.* Dated May 16, 1862.

The patentee claims, 1, The application of wood, divided into small parts, such as saw-dust, the leaves of trees, and the envelopes of certain fruits, for the cementation of juices of cast or forged iron, to form steel suitable for the manufacture of cutlery, rails, tyres of wheels, and other articles, as described. 2, The mode of converting the steel of cementation into cast-steel, as described. *Patent completed.*

1485. A. L. THIRION. *Improvements in the construction of railway and other carriages.* Dated May 16, 1862.

This invention consists in removing or relieving the axle from the direct weight of the carriage, and receiving it on metallic balls or bodies of a spherical or conical form, revolving between the plates or discs, which metallic balls or cones do not touch the axle; and in the mechanical contrivances or arrangements by which this object may be advantageously attained. *Patent completed.*

1486. F. B. ANDERSON. *Improvements in watches, and other time-keepers.* Dated May 16, 1862.

The object of this invention is to obtain a maintaining power with a fixed barrel, whereby the chain, and many parts in watches as now made, are dispensed with, and other advantages are gained. The patentee forms the barrel, and barrel-bar, or name plate, in one piece, and he also forms the ratchet, great wheel, and barrel arbor in one piece. He places in the barrel a collar or nut, with a square space in the centre, to fit the square of the spindle of the arbor, and he forms a hook on the outer surface of the nut, to take hold of one end of the spring contained in the barrel, the other end of which is fixed to the side of the barrel. He also forms the side of the barrel with apertures for the reception of the hook or stud, which holds the outer end of the spring, in order that the hook or stud may be shifted from one to the other, so that the tension of the spring may be regulated. The tension of the spring may also be regulated by shifting the collar to which the inner end of the spring is attached on the arbor. Again, in some cases, he makes the barrel and upper plate in one. *Patent completed.*

1487. D. C. LE SOUEFF. *Improvements in embossing metal plates.* (A communication.) Dated May 16, 1862.

This apparatus consists of a plunger working in a folding box, and attached to a suitable can by means of a rod; attached to this rod are various arms, which respectively actuate levers attached to the gumming plunger, the stamping plunger, the lever for opening the folding box, and the feeding carriage; in the interior of the folding box are weighted bell crank levers for enabling the flaps of the envelopes to be folded after the first descent of the plunger. *Patent abandoned.*

1488. G. DAVIES. *Improvements in the manufacture of ribs for umbrellas and parasols, part of which is adapted to the hardening of strips of steel generally.* (A communication.) Dated May 16, 1862.

The first part of this invention consists in hardening the strips of steel wire for the ribs of umbrellas and parasols, by passing the said strips, while red-hot, at an uniform speed through a hole in a trough containing water, or other suitable fluid, a constant steam of the latter being allowed to pass through the said opening in contact with, and so as to surround the strips of, steel wire, as described. This portion of the invention is applicable to the hardening of strips of steel generally. The second part of the invention relates to the construction of the joints which connect the stretchers to the ribs of umbrellas or parasols, and consists of a metal block cast to each rib, and arranged for connection to the stretcher in the manner described, so as to form with the end of the stretcher a cheap and durable joint, without weakening the rib at the point where the greatest strength is required. The third part of the invention consists of metallic tips or knobs, cast to the steel ribs of umbrellas and parasols, as described, so as to avoid the sharp, exposed, and otherwise objectionable ends of the steel ribs, as hereinbefore constructed. *Patent completed.*

1489. S. PEBERDY. *Knitting ribbed fabrics.* Dated May 16, 1862.

This invention consists in knitting ribbed fabrics by means of bearded needles combined with shields or guards formed substantially as described. The object of the invention is to dispense with the cumbrous and complex mechanism which has heretofore been used in knitting machines for produced ribbed fabrics. *Patent abandoned.*

1490. N. AMES. *A new and useful self-feeding card printing press.* Dated May 16, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1491. N. THOMPSON. *Improvements in stoppers or covers suitable for closing bottles, jars, and other similar vessels.* Dated May 16, 1862.

Here the patentee uses a plate or lid of earthenware, or any suitable rigid material, and which may be either made to lie flat over the mouth of the vessel, or it may be made with a conical or straight projection to enter the mouth of the vessel, which may be also coned or made straight to receive it. In either case he introduces a ring of vulcanized india-rubber, or other elastic or soft material between the bearing surface of the stopper or cover and the mouth of the vessel. In order to press the lid or stopper downwards, and secure it to the bottom jar or vessel, he uses a screw and nut; these are fitted into a recess in the centre of the upper side of the lid; by turning the screw the nut can be traversed up and down vertically, the screw being kept from traversing independently of the cover by collars, which bear on the piece which carries it, and which is attached to the stopper or cover. The nut carries two, three, four, or other convenient number of arms which radiate from it; these lie in grooves acting in guides to prevent the arms turning in the upper surface of the lid, and the said arms have claws, pin jointed, or otherwise connected to them at their ends, which catch into projections on the neck, or around the mouth of the bottle, jar, or vessel. Thus, by turning the screw the claws are caused to draw the stopper or cover downwards, so as to make a perfectly air-tight joint between it and the mouth of the bottle, jar, or vessel. The projections on the neck or around the mouth of the bottle, &c., are by preference recessed or undercut, so that the claws cannot be removed from the projections until they are released by the screw. The screw is turned by a key fixed on a suitable knob or handle, and which enters a corresponding recess in the end of the screw. *Patent completed.*

1492. F. STOCKEN. *Improvements in carriages.* Dated May 16, 1862.

This consists in applying folding steps to carriages, in the following manner:—An opening is made through the side of the carriage, by preference into the boot, or that part of the carriage which is over the fore wheels. This opening is closed by a door or panel, hinged to it at its under side, and this panel can be turned down, so as to stand at right angles to the side of the carriage. The folding steps are connected to the upper part of the door or panel, and, when the panel is turned down, so as to be at a right angle to the side of the carriage, the steps may be turned down, and made to descend to any desired distance. When the steps are folded up, the door or panel may be closed, and the carriage have the appearance of an ordinary carriage. *Patent completed.*

1493. B. SHARPE. *Improvements in the construction of ships and vessels, and in masts and spars for the same.* Dated May 16, 1862.

In constructing ships and vessels, of which the framework is principally of wood, in order to give greater strength and security to the several pieces of timber which form the frame, and other parts of the ship, the patentee places on one, or on each side of each frame, or piece of timber, a plate of metal of corresponding form, and passing from one end to the other of the frame, or piece of timber, so as to cover all the joints, and he secures the plates of metal to the timber by bolts; these metal plates hold the pieces of timber securely in their places, whilst the timber serves to keep the metal plates from breaking. He prefers to keep the metal plates out of immediate contact with the wood, by interposing tarred felt, paper, or other material, and also the coating the iron with another metal, by the process termed galvanizing. In order to give additional strength to ships, he arranges the deck beams so as to form a series of hexagons, and equilateral triangles, or nearly so. He does not claim a mere diagonal arrangement of the beams, in separate courses, as has been heretofore practised, but that intimate relation of all parts to each other, as shown in the drawings. *Patent completed.*

1494. A. V. NEWTON. *Improved machinery applicable to the cutting of leather, and other like uses.* (A communication.) Dated May 16, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1495. A. V. NEWTON. *Improved machinery applicable*

to the cutting out of boot and shoe soles, and kindred operations. (A communication.) Dated May 16, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1496. C. BINKS. *Improved methods of obtaining oxygen and chlorine gases.* Dated May 17, 1862.

This consists, 1, In causing, by any convenient means, a mixture of hydrochloric acid gas and oxygen gas, or a mixture of hydrochloric acid gas and atmospheric air, or atmospheric air mixed with a larger proportion contained in atmospheric air in its natural condition, to be brought in contact with concentrated or strong sulphuric acid, either under ordinary temperatures higher than ordinary ones, in order to effect the decomposition of the hydraulic acid with the liberation of its chlorine in the form of gas. 2, In projecting into, or otherwise bringing in contact with, liquid hydraulic acid (by any convenient apparatus or appliances), strongly heated oxygen gas or atmospheric air, or a mixture thereof, in order to effect the decomposition of the acid, and liberation from it of gaseous chlorine. 3, In certain methods of effecting the well known reactions between gaseous hydrochloric acid and oxygen gas, when these reactions are applied in the production of chlorine. 4, The object of the invention is to facilitate and economise the production of oxygen gas, and consists, first, in projecting into, or otherwise bringing into contact with, water (by any suitable contrivances), chlorine gas strongly heated as to effect, on such contact, the decomposition of the water, the result of a combination between its hydrogen and the chlorine forming hydrochloric acid, which is retained by the excess of water present, and thus liberating its oxygen in the form of gas. *Patent abandoned.*

1497. R. W. SIEVIER. *Improvements in naval warfare.* Dated May 17, 1862.

This consists in the application of an independant battering ram or rams to vessels of war of any class. *Patent abandoned.*

1498. R. DAVIDSON and T. JOHNSON. *Improvements in machines for washing and cleaning casks.* Dated May 17, 1862.

This invention consists of an improved frame or holder for containing two, three, four, six, eight, or more casks, and for securing the same while being washed or cleansed by hot water, or gravel, or chains. The improved holder consists of an inner frame containing a central shaft, with a right and left screw thread cut thereon, working through two nuts on, or connected to, two discs or platforms, between which the casks in one, two, or more tiers are placed. The discs or platforms are caused to move towards and recede from each other always equidistant from the main axis, for the purpose of securing and releasing the casks by giving motion in one direction or the other to the threaded shaft through a hand wheel keyed on one end thereof, or by simply making the upright shaft a fixture, by means provided for this purpose, and then turning the inner frame to the right or to the left, as may be desired, by laying hold of bars forming part of the inner frame. The holder is mounted, and is free to revolve round its own axis in an outer frame, made to revolve round its own axis, which is at right angles to that of the holder, by which means the casks are made to revolve in two contrary directions at the same time. There are various means of imparting these compound motions. *Patent completed.*

PROVISIONAL PROTECTIONS.

Dated July 24, 1862.

2100. J. Leetch, gunmaker, St. Marylebone, and B. Mathew, gentleman, St. James', Middlesex. New and improved methods of protecting the surfaces of iron or other metal work from oxidation, incrustations, or accumulations of any kind, more especially in the cases of ships' bottoms, steam boilers, and machinery.

Dated Oct 30, 1862.

2926. H. Eastwood, Elland, York, machine maker. Improvements in boilers and furnaces.

Dated Nov. 1, 1862.

2957. G. Haseltine, 100, Fleet-street. Improvements in coffins or burial cases. (A communication.)

Dated Nov. 4, 1862.

2984. R. A. Brooman, 166, Fleet-street, patent agent. Improvements in the manufacture of fringes and in machinery employed therein. (A communication.)

Dated Nov. 10, 1862.

3024. G. H. Sanborn, 99, Cheapside, merchant. An improved wringing machine.

Dated Nov. 13, 1862.

3056. T. C. and J. Eastwood, Marshall Mill, Bradford, York, machine wool combers. Improvements in machinery or apparatus for combing wool or other fibrous substances.

Dated Nov. 15, 1862.

3074. L. Croc, Aubusson, France, chemist. An improved ink to be used for the purposes of electric telegraphic printing or marking.

3076. J. Rimmer, Liverpool, coach builder. Improvements in hansom cabs.

3080. H. C. Whitburn, Orrell Colliery, Lancaster. An improved method of purifying sand to be used in the manufacture of glass, and for other purposes where silica is used.

Dated Nov. 17, 1862.

3090. C. Littleboy, Straffan, Kildare, Ireland, land steward. Improvements in implements for cultivating land.

Dated Nov. 18, 1862.

3092. J. Raphael, Upper Fountain-place, City-road, stick manufacturer. Improvements in umbrella, parasol, sunshade, and walking sticks.

3094. P. H. Klein, No 31, Rue du Grand Prieuré, Paris, engineer. Machinery for turning or shaping metals and other substances.

Dated Nov. 21, 1862.

3126. C. Hadfield, Hadfield, Derby, and W. A. Attkins. Improvements in compressing or dressing bricks and tiles and other materials, and in machinery or apparatus to be employed for such purposes.

3128. J. R. Napier, engineer and shipbuilder, and W. J. M. Rankine, civil engineer. Improvements in boilers, and valvular mechanism for steam engines.

3130. D. Saul, Swinton, Manchester, cotton spinner, and M. Morris, manager. Improvements in the manufacture of crinoline skirts, and in the apparatus employed therein.

3132. T. Walker, Birmingham, engineer. Improvements in utilizing sewage matters, and in the means or apparatus employed therein, part of which improvements is also applicable to raising and forcing other fluids.

3134. R. W. Swinburne, South Shields, soda manufacturer. Improvements in the manufacture of soda.

3136. J. Taylor, jun., Christchurch-road, Streatham. Improvements in the manufacture of tiles or moulded blocks for building purposes.

3138. S. Deacon, Alma-street, New North-road, builder, and C. Deacon, Rushton-street, St. John's-road. Improvements in tops, caps, and wind-guards for chimneys, and in apparatus for cleaning the same.

Dated Nov. 22, 1860.

3140. W. E. Gedge, 11, Wellington-street, Strand. An improved elliptical compass. (A communication).

3142. M. Mishores, Newcastle-street, Whitechapel. Improvements in the construction of handles for umbrella, parasol, or other like sticks from soft canes.

3144. C. Powell, Birmingham, watch manufacturer. Improvements in watches and other timekeepers.

3146. A. V. Newton, 66, Chancery-lane, mechanical draughtsman. Improvements in machinery for cutting corks. (A communication).

Dated Nov. 24, 1862.

3150. W. Clark, 53, Chancery-lane, engineer. Improvements in the means of obtaining a vacuum or partial vacuum, as applied in the manufacture of paper. (A communication.)

3154. E. Leigh, Manchester, mechanical engineer. Improvements in cotton gins.

3156. N. J. Amies, Manchester, smallware manufacturer. An improved fabric to be employed as a substitute for elastic, woven, or "braided" webs, and improvements in the method of manufacturing the same.

Dated Nov. 25, 1862.

3158. T. and L. Robertshaw, manufacturers, Bradford, Yorkshire. Improvements in the manufacture of textile fabrics, technically called "Moreens."

3164. G. Ranson, Eccleston, Lancaster, licensed victualler. Improvements in apparatus for preparing clay for brick-making and other purposes.

Dated Nov. 26, 1862.

3168. T. Fletcher, Rochdale, tin plate worker. Improvements in the construction of rollers, cans, spools, and bobbins, and in the machinery employed therein.

3170. J. Steinthal, Abbey Hey Works, Gorton, near Manchester, manufacturing chemist. An improved moulder's blacking.

Dated Nov. 27, 1862.

3178. F. W. Hartley, 55, Millbank-street, gas engineer. Improved means of obtaining certain products resulting from the manufacture and purification of coal gas. (A communication).

3180. W. T. Rowlett, Leicester. Improvements in machinery used in producing knit or looped fabrics.

3184. W. Clark, 53, Chancery-lane, engineer. Improvements in the preservation of animal and vegetable substances. (A communication).

INVENTION PROTECTED FOR SIX MONTHS BY A COMPLETE SPECIFICATION.

Dated Nov. 29, 1862.

3198. W. E. Gedge, 11, Wellington-street, Strand. Improvements in the construction of clocks or timekeepers. (A communication).

NOTICES OF INTENTION TO PROCEED WITH PATENTS.

(From the *London Gazette.*)

2100. J. Leetch and B. Mathew. Protecting the surfaces of iron or other metal work from oxidation, incrustations, or accumulations of any kind.

2134. W. Maughan. Beverages.

2137. J. Fourdrinier. Removing knots from pulp.

2146. J. Mackenzie. Shaping machines.

2148. E. T. Hughes. Refining the slag from furnaces. (A communication.)

2150. J. Norris. Ovens.

2151. C. T. Burgess. Stand for casks.

2158. W. E. Gedge. Securing the safety of trains moving on railways. (A communication.)

2164. G. H. Birkbeck. Preserving timber. (A communication.)

2173. C. Bedells. Manufacture of braces.

2181. G. A. Biddell. Railway crossings.

2182. J. C. Onions. Portable forges.

2183. R. and D. Nurse. Annealing pot.

2188. T. Onion. Propellers.

2190. J. Gray. Cleaning ships' bottoms.

2191. E. B. Wilson and M. Picard. Manufacture of iron and steel.

2193. G. Coles, J. A. Jaques, and J. A. Fanshawe. Grinding and polishing tools and surfaces.

2218. R. W. Ralph. Reaping machines.

2236. G. T. Bousfield. Manufacture of hat bodies. (A communication.)

2247. J. Combe and J. H. Smallpage. Holding and receiving cops when used for warps or sewing thread, or other purposes.

2275. L. D. Verstraet and E. M. Olivier. Manufacturing carbonate of soda.

2323. S. Boucher. Spinning flax.

2327. W. Whittle. Nails and spikes.

2332. S. Wilkes. Attachment for door nobs.

2358. M. Henry. Stuffing boxes and packings. (A communication.)

2391. W. Husband. Water-valves.

2452. W. E. Bovill. Applying oil and other fluid lubricating matters to machinery. (A communication.)

2477. J. Webster. Steam boilers.

2580. H. R. Fanshawe. Mode and means used in fishing.

2679. W. H. Muntz. Armour.

2887. F. Lipscombe. Purifying water.

2904. C. S. Duncan. Coating or conveying metallic and vegetable substances to preserve them from corrosion or decay.

2945. M. C. De C. Sinnibaldi. Manufacture of armour plates for ships and fortifications.

2957. G. Haseltine. Coffins or burial cases. (A communication.)

2978. J. McKean and T. Greenall. Sizeing or dressing yarns.

3002. T. Brown. Surfacing fibrous materials. (A communication.)

3044. G. Smith. Obtaining colouring matter.

3092. J. Raphael. Umbrella, parasol, sun-shade, and walking-sticks.

The full titles of the patents in the above list can be ascertained by referring back to their numbers in the list of provisional protections previously published.

Opposition can be entered to the granting of a patent to any of the parties in the above list who have given notice of their intention to proceed, within twenty-one days from the date of the *Gazette* in which the notice appears, by leaving at the Commissioners' office particulars in writing of the objection to the application.

PATENTS ON WHICH THE STAMP DUTY OF £50 HAS BEEN PAID.

NOTE.—Specifications will be forwarded by post from the Great Seal Patent Office (publishing department) on receipt of the amount of price and postage. Sums exceeding 5s. must be remitted by Post Office Order, made payable at the Post Office, High Holborn, to Mr. Bennet Woodcroft, Great Seal Patent Office.

THE

MECHANICS' MAGAZINE.

LONDON, FRIDAY, DECEMBER 19, 1862.

THE ATLANTIC TELEGRAPH.

THE President of the United States, in his massage on the 1st inst., said—"I have favoured the project for connecting the United States with Europe by an Atlantic Telegraph, and a similar project to extend the telegraph from San Francisco to connect, by a Pacific Telegraph, with the wire which is being extended to the Russian Empire." At a moment when the great American Republic is engaged in trampling out the greatest rebellion in history, when we should suppose every nerve is strained, and every moment occupied in raising, directing, and maintaining unparelled armies and navies—the President has found time to consider telegraphic plans submitted to him, and has offered to assist in their establishment. Probably he will soon have an opportunity to render the assistance offered, as we see that the Atlantic Telegraph Company is re-launched. We learn from a report of the extraordinary meeting of the shareholders of that company, held last week, that there is a good prospect of a sufficient amount of capital being raised to lay down another cable. The Right Hon. Stuart Wortley, who presided, confirmed many of the statements we made a fortnight since. It appears that the accidents which have hitherto happened to cables have invariably taken place in shallow water. There has not been a single farthing expended in keeping in repair lines lying in deep water. The whole of an Atlantic line, except the shore ends near the Irish and Newfoundland coasts, would be in deep and perfectly placid water on a soft bottom. There was, therefore, but little reason to apprehend that it would receive any injury when laid. Mr. Wortley used stronger language in condemning the manner in which the first cable was constructed and laid than we considered it our duty to make. He said he was in possession of facts which would enable him to lay bare a state of things which would explain why the first cable had failed. What he could not explain was the miracle by which the cable, under the circumstances, could work at all. It was "ill constructed," "hastily laid," "abused and injured," and "in an unfit state to go to the bottom of the sea." He, however, did not impute blame to any one.

When speaking of the proposed capital for the next cable, Mr. Wortley said that if it were to be of the same size as the one made, it would cost £600,000. Should they, however, determine to make a lighter cable, it might be made for £350,000 or £400,000. It was proposed to raise £600,000 capital by the issue of £5 preference shares. Should the cable be successful, the Government guaranteed 8 per cent. to the shareholders. As the £1 deposit per share was all that was likely to be called in for 12 months, the smallest capitalists in the country may become shareholders in the Atlantic Telegraph Company, and so become co-operators in carrying out a magnificent work. We think the directors have acted wisely in issuing £5 shares; and we are not surprised to hear that nearly £100,000 of capital have already been subscribed. We can only wish the company a speedy and a triumphant success.

THE SMITHFIELD CLUB SHOW.

(Concluded from our last Number.)

THE amount of ingenuity displayed in the lighter articles exhibited in the galleries of the Islington Agricultural Hall was, certainly, remarkably interesting. Many of the things there caused the same pleasure to a mechanician seeing them for the first time, as a neat algebraical expression would to a mathematician, or a well-preserved antique to an antiquary. These machines were exemplifications of the great neck and neck race between the powers of food-production, and those of the increase of human population. They also showed that, fortunately, mechanical, or, rather, constructive talent, is not scarce, as it seems to be developing itself in all classes of society. A powerful judgment is a rare thing, and to find it united with constructive ability, is still rarer. It may perhaps be said that just in proportion as we leave the heavier class of machinery to deal with lighter work, there is greater scope for ingenuity properly so called. Hundreds of arrangements and movements that do very well for light machinery, are totally inapplicable to engine work. As we leave the art of the machinist to enter the more scientific domain of the engineer, there is more demand on our science-directed judgment, and less on our ingenuity. The improvement of the steam-engine, for instance, is not to be sought for in ingenious combinations. It is to be found in a sound combination of the laws of chemistry, with those of construction.

EMERY'S THRASHING MACHINE.

Without pretending that we have chosen the *élite* of the smaller exhibits of the show, we will describe a few of the more novel ones. In this task, from international courtesy, we will give foreigners precedence, and will begin by describing a peculiar American thrashing machine, exhibited by H. L. Emery, the exhibitor of an American cotton gin, which was also to be seen in the western annex of the International Exhibition. This gentleman also sends an endless chain horse-power, to which we will allude.

This machine is somewhat of a novelty. The one exhibited was but 5 ft. high, 4 ft. wide, and about 9 ft. long, weighing complete about 800 lb., and was adapted to the 2-horse endless chain power, also shown, with a capacity, according to the inventor, for about 25 qrs. of wheat, or double that amount of oats, per day, and with a larger power it is said to do 35 to 50 qrs. per day of wheat.

This machine (see Figs. 1 and 2, page 403,) is provided with a cylinder, armed with a series of rows of teeth or spikes about 2 in. long, but inclining about 15 to 20 degrees backward from a radial line. Directly over this cylinder is placed an adjustable concave, armed also with corresponding teeth, also inclining from a radial line to correspond with those on the cylinder. This concave with its teeth may be adjusted and confined in any position required for the different kinds, conditions, and quantities of grain.

The feeding table is level, and placed on a plane with the axis of the cylinder, and the grain and straw are carried over the cylinder and between it and the concave, thereby facilitating the feeding process, and preventing any hard substances being drawn in to its own injury or that of the attendants. A flue is attached to the machine to receive the dust from the feeding side of the cylinder, which flue conducts it over the concave and into the machine at the discharging side of the cylinder, whence it escapes with the chaff from the fan.

In this process of over-shot threshing the straw and grain become thoroughly separated from each other, the grain leaving the cylinder at a lower line than the straw, which last is carried out nearly horizontally from the concave. In this machine the first and almost perfect separation is said to be secured, and the grain prevented from flying into the straw again, as is the case, more or less, with all under shot machines. This is done by means of an endless apron of cells or boxes, which is placed in an inclined position at the discharging side of the cylinder, which endless apron revolves rapidly in the same direction the grain and straw is moving. These cells receive the grain as it is discharged from the cylinder, while the straw passes on over it to the revolving-beater or rake, and thence along the riddles and out of the machine. The rapid movement of the apron of cells is said to avoid the concussion of the grain upon it, and the consequent breakage of the kernels or wear of the cells themselves. The revolving beater or rake is placed at the upper end of the apron, and is of a triangular shape, and is hung upon hollow journals. Through these journals is passed a shaft, which, inside the beater, is of a crank form, with the crank downwards. The ends of these teeth, which are of steel wire, are attached to this shaft, and at the other end they project through the beater at an angle, and as the beater revolves these teeth protrude in and out at each revolution. The purpose of this beater is to accelerate the passage of the straw, especially long straw. It also opens it up, so that whatever kernels of grain may remain in it can fall out upon the riddles.

There are two horizontal riddles, one above the other, extending from beneath the beater quite out to the end of the machine. The upper one is perforated with holes for the ready passage through it of the chaff and grain, which is caught and conveyed back towards the cylinder to the fan near the lower riddle. This upper riddle is also provided with a series of agitating fingers laying flat with it, but having a vertical motion, which serve to keep the straw in suspension, and to aid it in its passage from the machine. The shoe containing the screens and the discharging spouts is placed directly below the endless apron of cells, while the fan is directly beneath the feeding-table and cylinder.

The motion and power is communicated from the propelling power to the cylinder by the main band, and this same band gives motion to the fan. All the other motions are produced by a pair of eccentrics upon the fan-shaft, and one small band to the beater and apron of cells from the same fan-shaft.

In the centre of the machine is placed a rocking-shaft, with arms extending upwards; the excentric rods which are attached to the lower ends of the arms giving to them the motion. From these arms, at different distances from the centre of motion, the several other parts, such as riddles, shoe, &c., owe their action. The shoe, riddles, &c., are all hung with pendulum connections, in such positions as to produce the desired effect; and in such wise that each motion is counterbalanced by some other.

The horse-power was on the ordinary American endless chain principle, but with some improvements. The shafting and gearing are so arranged as to produce a variety of speeds required for propelling different machines. There is a governor attached to the running gear, which controls the speed within any desired limit, and may be adjusted to different speeds found desirable for the animals. This is said to enable horses, bullocks, mules, &c., to be used without harness.

On the shilling evenings there was a most uproarious crowd of people round this machine, insisting on getting on the endless chain, and putting it to work. It was thus put to a rather severe test.

THE COW-MILKER,

Another American invention, that excited much attention at the Great Exhibition, was also sent to the Smithfield Club Show, by several exhibitors. This is, namely, the "Cow-milker," the india-rubber pump, and india-rubber "teat-glove" (if we may use such a term), which is familar to most of our readers. It is said to fail in the hands of a careless farm-servant, as, indeed, most machines would. When its action is carried on too long, it is said to pump blood from the cow, as well as milk. Some authorities aver that all the teats of a cow are not equal in their milk-producing powers. This machine, however, is made to act equally on all. If the sum for which the Yankees are said to have sold this invention in England be the correct one, the machine made a good beginning in milk-pumping powers. To a "cute Yankee" the Goddess of Science herself is but a good big cow with plenty of milk.

Another foreign invention that excited some attention was

A HORSE-CLIPPING MACHINE,

exhibited by Messieurs Carrere de Nabat, of Paris. We saw it at work in a stable close to the Islington Hall, and as far as we could judge, during a short inspection, it seemed to do its work very completely. It was patented some two or three years ago in England, and the following wood-cuts show it in its then shape.

This apparatus for shearing, more especially horses, asses, and cattle, consisted of two metal supports screwed the one to the other; in these supports was placed a shaft square at one end, and carrying at the other a toothed wheel, gearing into a pinion fixed upon another shaft, this shaft carrying two plates or wheels with arms having slits in them, in which the ends of steel blades are secured by press screws. These spiral blades rubbed against a lower blade. This latter blade was attached to the two supports by two pivots, and beneath was a steel comb furnished with a spring, tending to raise the said blade, the comb being screwed to the supports. The apparatus, when used, was to be held in one hand, while the other, by means of a "Breguet" key, turned the first-mentioned shaft, and thus nearly every part of the animal could be passed over and shorn close or otherwise at will, the length of the cut being regulated by the thickness of the comb.

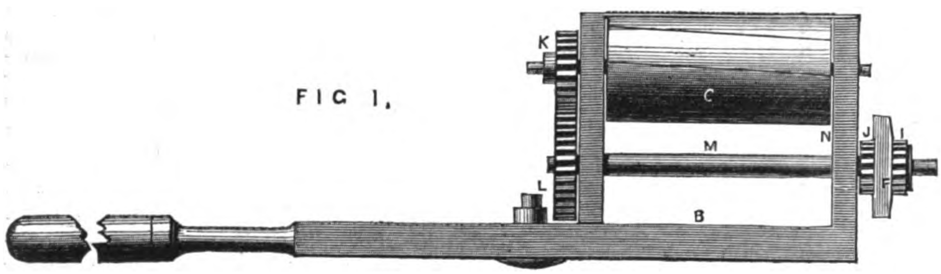
It will be at once seen that the instrument is substantially a small lawn-mower. It is moved against the grain of the hair of the animal. The legs and the lower parts of the chest and head must still be clipped by scissors, but this may be done while the other parts of the animal are being shorn by the machine. Since taking out their first patent the inventors have greatly improved the way in which the motion is transmitted to the little "lawn-mower." A flexible chain is used for this purpose, formed of articulated links, and four wires of tempered steel. This chain is caused to rotate by means of a little portable frame, worked by a hand labourer. It is held down by the left hand, while the right works a lever up and down. By means of gearing the blades are caused to revolve at the rate of 7,560 revolutions per minute. Each stroke of the lever causes four revolutions of the chain; the chain increases this by three times, and the roller being fitted with seven knives, thus takes 126 cuts for each stroke of the lever. The lever can be worked up and down about 60 times per minute. According to the inventors, two horses can be completely clipped in five hours, requiring three men — the operator with the "hair-mower," a labourer to drive the chain, and, thirdly, the clipper, with ordinary scissors, for doing the legs and lower parts of the chest and head. It is said that clipping has been tried with success by an eminent French grazier, as a means for quickening the fattening up of oxen. Some time before the International Exhibition, Messrs. De Nabat showed their machine to the French Commission appointed by the Emperor to choose the French machinery they considered worthy of being sent to the London Exhibition of 1862. This apparatus was rejected by the commission, the machine being deemed impracticable. After divers explanations being given to the commission by the inventors, a committee was formed to examine the machine. None of these gentlemen appeared at the promised time, finding it more convenient to refuse the application altogether for exhibiting the machine in London. This is another specimen of the proverbial wisdom of corporate bodies. The inventors therefore determined to exhibit the machine in England on their own account. Considering what mechanical rubbish was sent to the Exhibition in some instances, the exclusiveness in this case seems rather "de trop." The inventors informed us that five horses belonging to her Majesty, in the Queen's stables, had been lately clipped by this machine.

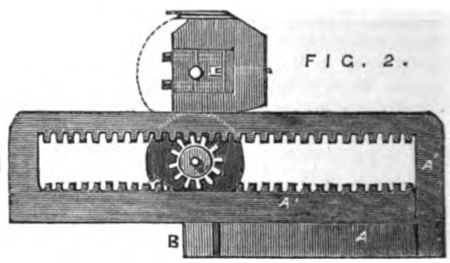
HOUSE'S CRUSHING MACHINE.

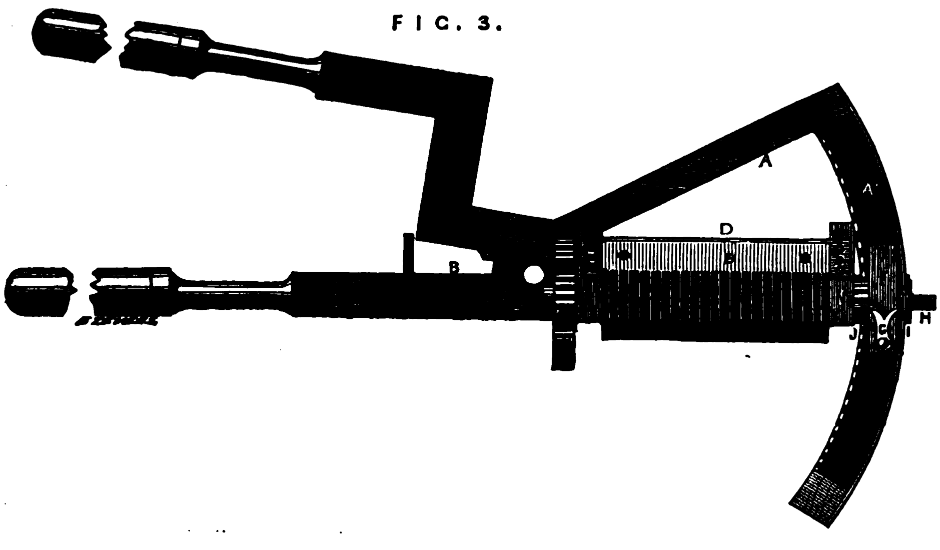
The accompanying engravings show a machine for crushing guano, grain, oil-cake, mortar, cements, and similar substances. It is certainly absurdly simple, and it is said to be very efficient. The rollers are shaped somewhat like the V-grooved gearing applied to several machines exhibited in the western annex. Instead of the grooves touching, intermediate spaces are left between the rollers, through which the substances to be crushed are passed.

These rollers may be either made in one or more parts, and composed of steel or chilled cast iron. In place of being cylindrical, they are formed on their surfaces with a number of alternate V grooves and projections, the projections of one roller working into the grooves of the opposite roller. These grooves and projections may be smooth on their outer surfaces, or they may have a series of notches formed on them, with a view to the effective disintegration of the substances. When these rollers are made in several parts, each part will consist of a disc, having its periphery bevilled on each side, so as to present a Λ or knife edge. By placing a number of these discs upon a square shaft, a roller of the description referred to will be obtained, each disc being formed with a series of teeth or notches on its bevilled edge, or made smooth as before described. In some cases it is proposed to use, in combination with these rollers, a feeding roller, provided with a number of projecting cups, such roller working at the bottom of a feeding hopper, and tending to feed the substance in a regular manner to the rollers, the feed rollers being driven by suitable gearing from the reducing rollers. It is proposed to use when requisite a vibrating

HORSE-CLIPPING MACHINE.







HOUSE'S CRUSHING MACHINE.

Fig. 1.

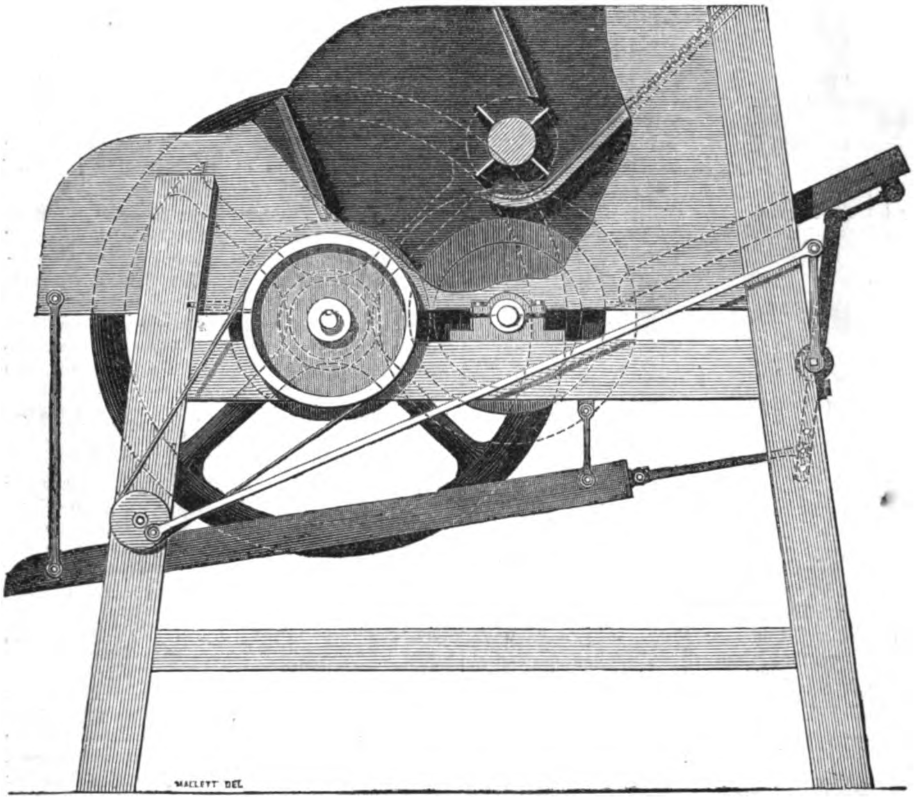


Fig. 2.

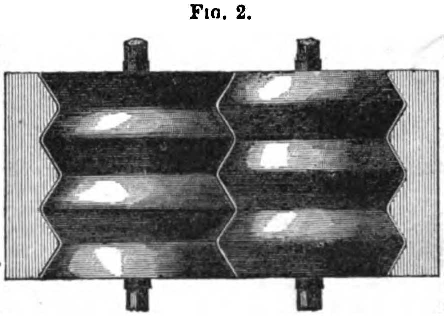


screen in combination with the above mechanism, for the purpose of sifting the substance as it leaves the rollers. In order to keep the rollers clean and prevent them from becoming clogged, a scraper is applied to one or both rollers.

Fig. 1 of the engravings represent a side elevation of the machine, with a portion of the side partly broken away to show the internal arrangement; and Fig. 2 is a detailed plan of the peculiar V rollers and scrapers in connection therewith.

The main framing of the machine, to which are applied the two side pieces, is partly broken away, as above described; and the two rollers, having annular V grooves, *e e*, are provided or not with teeth, or serrations, as required, upon the surfaces of the grooves. The scraper plates are secured to the framing, and so shaped as to correspond to the peculiar form of the rollers; the main driving shaft may or may not form the axis of one of the rollers; it is provided with a fly-wheel, and driving handle or driving pulley, and carries a spur pinion, or small spur wheel, gearing into a large spur wheel fast on the axis of the second roller; this wheel gears also into a pinion, or small spur wheel, fast on the axis of the feed roller, which is provided with spikes, or cups, on its surface, as before described. On the opposite end of the main driving shaft there is keyed a grooved pulley, which transmits motion, by means of a band, to the small pulley; this pulley carries an eccentric pin, which imparts a longitudinal vibrating motion to a connecting rod, jointed at its opposite end to a rocking lever on the transverse rocking shaft; to the middle of this shaft is keyed a second rocking lever, projecting both above and below the same, the upper end being coupled by means of a link with a vibrating feeding spout, whilst the lower end is connected by a link with the top of the inclined vibrating riddle or sieve, the lower end of which is suspended by links from the side pieces of the machine; the material or substance to be operated upon is fed in from the vibrating spout (if the spiked feeding roller is not required), or from the stationary feeding hopper if the action of the feeding roller be found requisite, and is thence carried (if fed from the latter hopper) by means of the feeding roller to the crushing rollers, one of which in some cases may revolve faster than the other, so as to give a draw-crushing action, and finally drops on to the vibrating sieve or riddle, should a screening action be found to be desirable.

RANSOME'S HARROWS.

We alluded last week to Messrs. Ransome's harrows. The following remarks and illustrations (see next page), give a description of this invention. This harrow was, we believe, also exhibited at the Battersea Show, last spring.

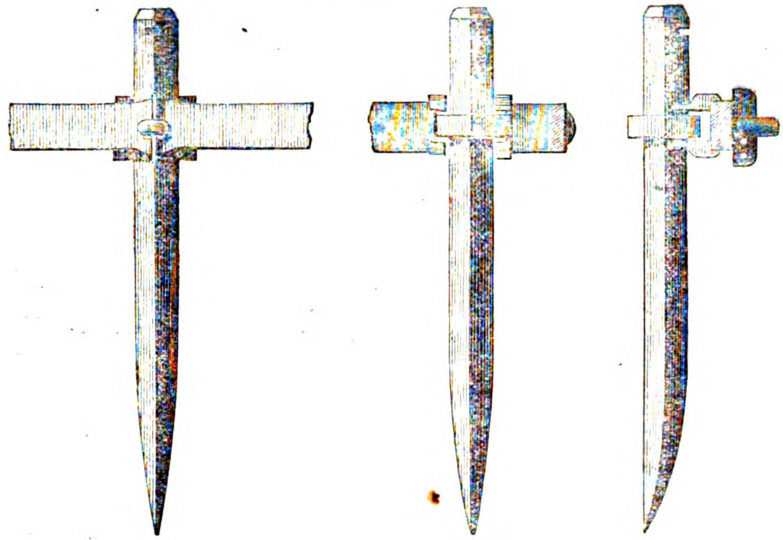
In constructing harrows having rigid frames, it has been usual so to make them that the same fastenings which held the tines or teeth to the frame also secured the parts of the frame the one to the other. According to this plan the fastenings of the teeth are made independent of the fastenings of the frame in the following manner :—The framework is composed of longitudinal and transverse bars, either rivetted or bolted together, and the teeth are attached to the cross bars by means of metal loops or clasps, which pass round the teeth, and are tightened up by means of nuts, cotters, or otherwise. Between the tine or tooth and the bar a casting, having a groove in it, is interposed to form a suitable bed for the tooth, the casting is prevented from shifting on the bar by lugs or otherwise, and it is held by the loop or clasp which embraces the tine or tooth. The tooth is made square in section, and has V-formed grooves to the bed casting to correspond therewith. In place of placing castings on the frame to receive the tines, the cross bars of the frame may be made of malleable cast iron, and suitable grooves or notches may be produced in them at intervals where the teeth are required; or the frame may be made of wrought iron with suitable grooves or notches, or with some forms of tine or tooth the grooves or notches may be dispensed with. The advantages of this form of harrow are, that any tooth can be taken out and a new one put in with less trouble, and independently of the fastening of the framework, and also that the strength of the tooth is preserved in the mode of attaching it to the cross bar.

This plan has also for its object the forming harrows in such a manner that they shall have greater play and freedom in work than the ordinary rigid frame harrow. With this object each tine or tooth of the harrow is attached to an axis at a distance in front of it by a bar or lever which is free to turn on the axis. The axis of the leading tines or teeth of the harrow is immediately connected with the draught, and the axis of the bars or levers of each following row of tines or teeth is carried by the rear ends of the bars or levers of the row immediately in advance. Or the teeth of each row, with the corresponding bars or levers, may be formed together as a rigid frame, and the successive frames forming a harrow may be jointed together in the manner already described. The harrow may, as is practised with harrows of the ordinary construction, be drawn either end foremost. Thus it will be seen that the rows of tines or teeth are not rigidly connected with each other, and consequently the harrow is able to adapt itself to uneven or rough land, and it is less liable to clogging, owing to the parts not being rigidly connected. The figures show one way in which this plan is carried out, cotters being used, although, of course, screens may also be adopted. There is a notch in the tooth into which a projection on the metal bed catches for the purpose of preventing the tooth from sliding up or down; although only one notch is seen in the figure, it is obvious that by making several the teeth may be made to project any required distance below the frame or transverse bars.

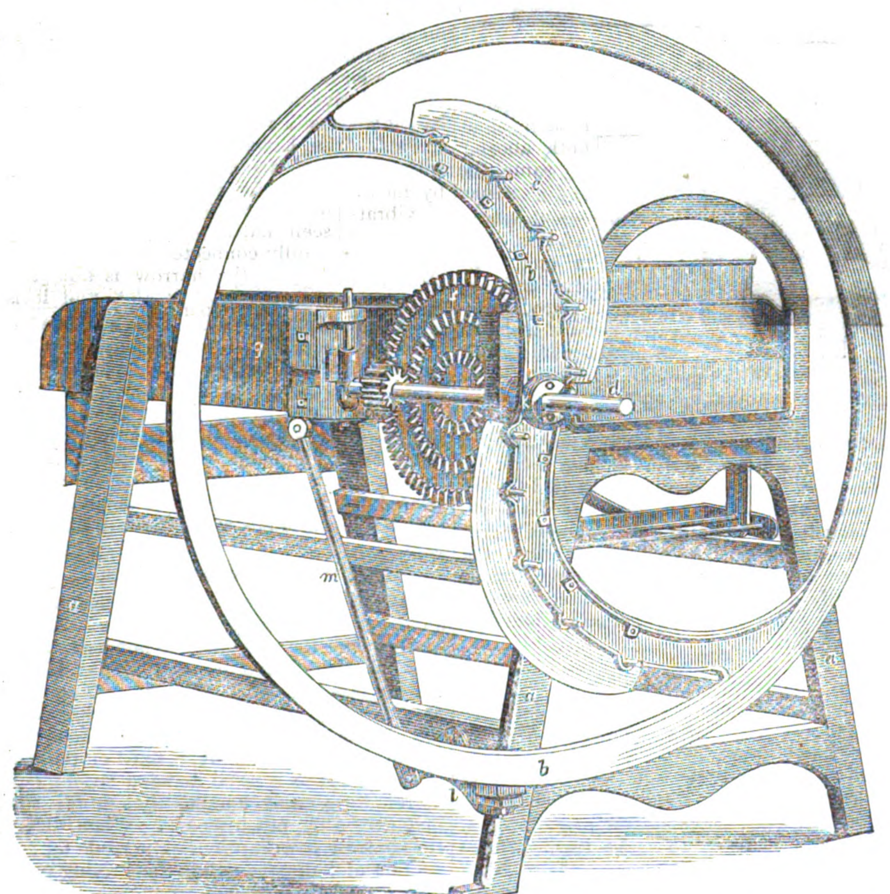
WARREN'S CHAFF CUTTER.

The following seems a neat arrangement for a chaff-cutter, sent by Mr. Warren. A large placard over the machines announced that it was "*the long looked for chaff-engine, king of the chaff-cutters, &c.*" This is puffery more worthy of a quack toothdrawer than of a respectable machinist. The fly-wheel, with the knives carried thereby, is fixed on the main shaft, which, as is usual in hand machines, is driven by a crank handle, though the shaft may driven by other means. When driving the shaft by power, provision is made for connecting and disconnecting the driving pulley on the shaft by means of a clutch box slid on the shaft by a hand lever. The driving shaft is at right angles to the ends of the feed rollers, and it gives motion thereto by means of a pinion gearing with the teeth of a face wheel, which turns on a stud at the side of the trough or box of the machine

RANSOME'S HARROWS.



WARREN'S CHAFF-CUTTER.



next the driving shaft. The face wheel, by means of a pinion thereon, gives motion to toothed wheels fixed on the axis of the feed rollers next the face wheel, so that the face wheel is geared by its pinion directly with the toothed wheels on the axes of the feed rollers, in place of the axis of the face wheel being extended to the other side of the trough or box of the machine; and in combination with this arrangement, the face wheel is formed with three, or more than three, circles of radial teeth, and the driving shaft crosses the centre of the face wheel. The pinion on the driving shaft, which gives motion to the face wheel, is capable of being slid along the shaft, in order that it may gear with either of the circles of teeth on the face of the wheel, and, when slid along the shaft, it moves correctly in a radial line to and from the centre of the face wheel. The boss or nave of the pinion on the driving shaft is made with a groove all round it, which is embraced or partly surrounded by the end of a bar, which is made capable of sliding (in a suitable projection or bearing fixed to the side of the trough) to or from the centre of the face wheel, and this sliding bar is made capable of being fixed and retained in position when the pinion is in a correct position to gear or work in any one of the circular rings of radial teeth on the face wheel.

HUNT and PICKERING exhibited, amongst other things, some scythes fixed with a key or wedge into a gas-pipe handle. This attachment seemed a neat one, but the instrument, as a whole, did not seem very handy.

PAGE and Co. sent a number of articles, among which we remarked a rather neat oil-cake breaker, and a combined horse-hoe. We will illustrate and describe these next week.

H.

GROOVED FRICTIONAL GEARING.

ACCORDING to the *Scientific American*, frictional gearing, instead of toothed wheels, seems to be coming into extensive use in America. The mode by which the motion is communicated is as follows:—The peripheries of the wheels are provided with Λ-shaped grooves around their circumferences, the extreme points of the Λ being removed to insure a good bite; and each Λ fitting into the recess formed by a W on the other wheel; the smallest possible pressure is thus made to give a very large amount of force. It is calculated that the adhesion or driving hold of the surfaces of these grooved wheels is about nine times that of plain surface frictional wheels. When working at 1,000 circumferential feet per minute the contact pressure requisite for transmitting a standard horse-power is 22 lb.; at double that circumferential speed, 11 lb.; and in the same relative proportions at other speeds; a wheel 8 ft. in diameter, working at 40 revolutions per minute, gearing with a pinion, requiring a large amount of pressure to transmit 100 indicated horse-power. This system of gearing seems to be thoroughly adapted both to heavy and light machinery; and wherever there is liability to sudden concussion or strain they are invaluable, since, from their very principle, it is evident that they cannot be damaged. In case of a sudden jerk, a slight and immaterial slip is the sole inconvenience, the wheels being left in quite as good order after the jerk as they were before, instead of, as would be the case with ordinary gearing in use, broken teeth having to be repaired before the working could be continued. The smoothness with which the frictional gearing works is remarkable. Some of the wheels upon this system have been in use many years, and continue to give the greatest possible satisfaction; and it is considered that where the wheels are properly proportioned to the work to be done, they are more durable, and transmit power with less waste by friction, than is incurred by using toothed gear. We allude to this kind of gearing in our article on the Smithfield Club Show.

AMERICAN ORDNANCE DEPARTMENT—GUNS AND IRON-CLADS.

CAPTAIN J. A. DAHLGREN, chief of the North American Ordnance Department, has presented a long report to the Secretary of the Navy, from which we condense some interesting information. He states that there is now a prospect of obtaining a considerable amount of nitre for the manufacture of gunpowder, from our own resources, but the chief supplies for the whole world are still in the hands of the British, and are obtained from the East Indies. There are seven private establishments fabricating cannon for the navy, viz.:—Knap and Rudd, Pittsburgh, Pa.; Alger and Co., Boston, Mass.; R. P. Parrott and Co., Cold Spring, N. Y.; J. Sparrow, Portland, Maine; Hinckley and Williams, Boston, Mass.; Z. Chaffee,

Providence, R. I.; and Seyfert and McManus, Reading, Pa.

IRON-CLAD SHIPS.

The use of solid shot fired from 42-pounders at sea, ceased at the battle of Navarino. After this Captain Paixhan introduced shells. The terrific effects of these were first really displayed at Sinope, by the Russians. In 1855 the French first used three iron-clad vessels at the Kinburn forts, and none of the Russian shot was able to pierce the plating. The first seagoing iron-clad frigate built was "La Gloire," and England soon followed the example with the "Warrior." These are large vessels, of great draught. The American coast being mostly shoal requires vessels of light draught, hence they are inaccessible to heavy iron-clads like the French and English frigates. Vessels of the "Monitor" and "Ironsides" classes are likely to suit our present purposes. Captain Dahlgren states that Whitworth first demonstrated that thick iron plating, backed with wood, could be pierced with shells. The 11-inch guns of the "Monitor" were chiefly designed for shells, which were computed to have an initial velocity of about 1,120 ft. per second; but this class of gun is capable of throwing 169 lb. solid shot with 30 lb. of powder, and an initial velocity of 1,400 ft. per second. The "Merrimac" was armed with 9-inch guns; their shot did no material damage to the "Monitor;" the damage which the shot of the latter effected is not known. The wrought-iron shot furnished to the "Monitor" weighed 186 lb. If fired with 15 lb. of powder, their initial velocity would only have been 1,050 ft. per second. The "Monitor" only fired 42 shots at the "Merrimac," and many of these failed to strike, from the difficulty of aiming with precision. The "Monitor" and "Galena" failed to make any impression in the attack on Fort Darling, on the James River, because their guns had to be so much elevated.

GUNS FOR IRON-CLADS.

Rifled shot is the most accurate at long ranges, but when they strike and are deflected, they tumble over and have a very erratic flight. Such shot, therefore, have no capacity for ricochet firing, which is one of the most certain modes of operating in naval service when round shot is used. Rifle shot have greater penetrating, but less percussive power than round shot. The rifle gun, however, is gradually making its way into the service. The "Galena" was fired upon at Fort Darling with round shot from 64-pounders. These passed through her plating, and the entire structure of the vessel was much damaged.

An 11-inch gun can be fired once per minute with a well-disciplined crew; but some improvement must be made before a 15-inch gun can be fired once in three minutes. The "Roanoke," which is being converted into an iron-plated turret ship, will be able to throw 2,700 lb. of shot at once. The effect of her shell of 330 lb., and solid shot of 450 lb., from 15-inch guns, will be damaging beyond former experience. One of the 15-inch guns has been tried on 5½-inch iron plates backed with 18 in. of oak, and placed at 200 yards distant. The shot passed through this target with ease. One of the 11-inch cast-iron guns (weighing 16,000 lb.), has been fired 155 times, with charges varying from 20 to 30 lb. of powder and shot of 165 and 169 lb. This gun does not exhibit any signs of giving way. A great number of experiments with these cast-iron guns afford proof that they are as strong and durable as the forged British guns.

COAST DEFENCES.

Capt. Dahlgren states that batteries of masonry should not be exposed to rifle cannon. The exterior of stone and brick forts should be covered with iron. The low stone forts at the Narrows of New York are not well calculated to hinder the passage of an iron-clad vessel. The earth works on a high elevation are superior. Steam rams will be of little use, unless their speed is greater than that of other vessels. Floating iron-clad batteries should be employed to assist forts in case of an attack by iron-clad frigates.

ARMOUR PLATES AND WOOD BACKING.

SIR,—I do not write with the intention of continuing the discussion between "Civilian" and myself, for it does not require prolonging. I acquiesce most cheerfully in your decision to close it, for no one can fail being struck dumb in admiration of the gallant impetuosity with which your correspondent has invited your readers to a scientific affray, whilst trailing his coat behind him; or help cowering before the charming confidence with which he has handled his shillelagh, although a novice, as he confesses himself, in the science of his weapon. I am sure I retire from the scrimmage in dismay, happy enough to escape, though with plenty of kicks, from all the braining blows. But, dropping the appropriate figure, I do claim to be heard in protestation against two serious misrepresentations. The one refers to an opinion, the other relates to a practical suggestion; but in respect to neither do I find it to be agreeable to be held up to your readers in a light that would indicate I had taken leave of my senses. Besides, I never will allow, if I can help it, a misrepresentation, when it is founded on an unfair quotation, to pass unnoticed.

"Civilian," by adroitly quoting the following portion only of a sentence, represents me as advancing an independent proposition, and one so insane and vague as to be sheer nonsense:—"It is obvious at a glance that for all which is under water wood is a relief and iron is a burden to a ship." Now this as it stands may be either true or false, according as it is supplied with the condition of a variable or a given magnitude of displacement for the vessel to which the wood or iron is applied. My words were—"When the *defences* are placed outside [the vessel, as in the case of the "Warrior,"] it is obvious at a glance that for all which is under water, wood is a relief and iron is a burden to a ship;" and thus by recognising the special case of already existing ships, and the additional displacement given to them, sense is restored to the quotation, and correct sense too, which neither "Civilian" nor any one else is able to gainsay.

Allow me here the opportunity, Mr. Editor, without going into fresh matter, to give a little expansion to and explanation of my former remarks, for they may not have been clearly understood in other quarters. On the other hand then, when the displacement has been made a given quantity, and has been charged with all the weight consequent on construction (but the question whether wood or iron is better for that purpose is an extraneous one, which we need not, *apropos* to this subject, be troubled about), any further addition to the weight for purposes of defence will be altogether a burden, whether wood or iron be employed; but whether wood or iron is the greater burden—and here is the gist of the subject—or how much more a burden one of them is than the other, protection against shot being equal, is a problem which neither "Civilian" nor myself can solve, because we are in want of the data. From a calculation full of assumptions, I have stated that I thought they may be on an equality in this respect, but I do not wish to commit myself to that opinion. Experiments only can determine. But whether the result be in favour of wood or iron, still the curious conclusion holds good which I pointed out in my last, that each defence being carried to the extreme, the ship sinks in the one case and floats in the other. The fact is, that increasing thickness of the iron defence must be governed in the main by a corresponding advance in the least magnitude of displacement compatible with proper flotation; and if we are to provide security against the mighty pieces of ordnance that are about to be brought into use, so that their shot shall not endanger the sinking of the vessel, that magnitude of displacement will, I fear, be a very large one, even with great sacrifices of seagoing qualities. But to a wood defence there is no limit imposed by a minimum of displacement; protection can be so augmented, and can be afforded to vessels so small, that their sides shall meet, when, if [illegible]ged, they will will be more efficient than ever as against being sunk; although, doubtless, it is an advantage gained at the expense of many valuable properties. But sacrifices will have to be endured all round. Everything depends on what property we propose to make paramount. If vessels are to be made unsinkable, they must give up roaming the seas as steamers, unless they are of extraordinary magnitude. We shall have to go back to sail power, and to little better than rafts in construction, for all fight craft, or else with certainty to go to the bottom in the first hostile encounter. The Americans seem to understand and to be acting on this principle of immense thickness in the wood portion of the defence, but all such vessels, except the very large ones, will, of course, be coast and harbour bound, as steamers.

The other misrepresentation, the subject of animadversion, relates to my proposal for armouring ships. "Civilian" says, that I hold "the eccentric idea of soldering iron plates in one mass over the hull of a ship." Now it is very curious, but I never said anything about iron plates, nor about soldering them together, nor have I proposed to *solder* plates of any kind together. The idea is absurd, and I do not wish to have the credit of it. What I proposed, was, to lay down upon a wood backing a course of steel plates 3¼ in. thick of a moderate size, and then to overlay them with a course of gun-metal plates 2¼ in. thick, and as large as possible. These gun-metal plates are to be fused to each other at their edges, that is to say, they are to be burned together, as it is technically called, into one mass (not to the steel plates beneath them) just as the parts of a bronze statue are, and I see no more difficulty in the one case than in the other. It would be necessary to guard against injuring the wood backing by the heat passing through the steel plates, but this may be obviated by a thin non-conducting coat of plaster and brick dust to prevent contact between the heated metal and the steel plates. But instead of this old-fashioned method of burning metals together, the modern appliances of the blow pipe with coal gas and common air, to say nothing of the cheap oxygen gas with which we are to be favoured, would accomplish the purpose with greater facility and with much less conduction of heat. The scheme is practicable, but costly. Only experiments could tell how much more efficacious for resistance such a defence would be than an equal weight of wrought iron.

I am, &c.,

Dec. 15. BENJ. CHEVERTON.

P.S.—Will you allow me to add, for the sake of some who may be curious on the subject, that in the full investigation of the action of a projectile on armour plates, the concentration of the action in regard to time must not be overlooked, although its concentration in regard to space, as being less recondite for discussion, has alone engaged my attention.

PATENT ELECTRIC BELLS.

ONE of the most important novelties in bell ringing and, at the same time, the latest introduction of scientific appliances to our dwelling-houses, is the new system of ringing bells by means of electricity. We have rung bells on one side of the Atlantic by batteries fixed on the other, but until now we have never thought of having a similar communication between our dining-rooms and our kitchens, between our drawing and bed rooms and our servants' halls. We have hitherto pertinaciously stuck to the old-fashioned system of cranks, levers, and copper wire, only occasionally economising labour by speaking-tubes. The invention, of which Messrs. Newall and Co., of Sloane-street, are the sole agents, possesses many great advantages. 1st, It is simple—a battery charged with chemicals is placed in any unappropriated corner of the house to keep company with the gas-meter; two wires are attached to the zinc and copper poles by which the electricity is generated and carried off. These two wires being brought together in any part of the house, causes one or more bells to ring. 2nd, It is inexpensive, as the cost of replenishing the chemicals of a battery large enough for 20 bells does not exceed 5s. a-year. 3rd, It is universally applicable; it can be taken over any uneven wall or floor and in any tortuous direction without affecting the result; it can be applied to the desks of railway stations, banks, or with equal facility to the tables of their managers. 4th, It is easily worked; it can be worked by the faintest pressure of a nob, by a lever, or by almost an infinite variety of methods; 5th, The wires can be coated with silk or cotton of any tint, so as to accord with the decorations of a room, or to be practically invisible upon them; it can be fixed to shutters, doors, and windows at night, and be made to give thence an alarm by, if required, ringing every bell in the house. There seems, in fact, no limit to the usefulness of these electric bells for domestic purposes. They have been already fixed in Windsor Castle and in several other large buildings, where they

have given every satisfaction, but as it may be difficult for such of our readers as feel interested in them to see them there in operation, a visit should be paid to Messrs. Newall's premises, in Sloane-street, where the full value of the invention can be seen, and any doubts about their efficacy be immediately dispelled.

INTERNATIONAL EXHIBITION.

JURORS' REPORT.

Class X., Section A.—Civil Engineering.

JURY.

A. Bommart, France; General Inspector in the Imperial Corps of Bridges and Roads.
J. Kelk, London; Contractor.
Koch, Zollverein; Government and Architectural Councillor, Berlin.
J. Leclerc, Belgium; Inspector of Agriculture and Engineer of Bridges and Roads.
Maurice Loehr, Austria; Imperial Councillor of the Board of Trade and Public Works.
C. Manby, F.R.S., London; Hon. Sec. to the Institute of Civil Engineers.
Thos. Page, London; Civil Engineer.
Sir J. Rennie, F.R.S., F.G.S., President of Section, London; Civil Engineer.
Marquis of Salisbury, K.G., Chairman, London.
Cesare Valerio, Italy; Member of the Italian Parliament.

Associates.

Baron Baude, France; Engineer to the Imperial Corps of Bridges and Roads.
Mille, France; Engineer-in-Chief of Bridges and Roads.

I.—Bridges.

There are few more important and difficult operations in civil engineering than the construction of bridges across great rivers, estuaries, and valleys, and none which require greater skill and judgment in design and construction, in order that the works may be properly adapted to fulfil the object in view in the best manner and at the least possible cost; and, it is but justice to say, that amongst the numerous objects of this class submitted to our examination, there are works of the highest merit, and which have been most successfully carried into effect.

Amongst the most prominent and important of this kind may be mentioned the class of wrought-iron tubular girder bridges exemplified by the remarkable and extensive bridge erected across the river St. Lawrence, at Montreal, for the Grand Trunk Railway in Canada. This bridge was based upon the system introduced in the "Conway" and "Britannia" bridges, on the Chester and Holyhead line of railway.

All these three bridges were designed by and constructed under the direction of the late Robert Stephenson, M.P., F.R.S., and both he and the resident engineers and contractors are entitled to the greatest possible credit for the novelty, originality, and boldness of the designs, the admirable and ingenious contrivances employed in the structures as they have been carried into effect, as also for the very complete manner in which they have answered the objects for which they were designed and constructed, so as to offer the least possible obstruction to the navigation, and at the same time to afford the greatest and most substantial accommodation to the traffic passing over them. They were necessarily attended with great practical difficulties in the execution, not only in combining and putting together the vast masses of wrought-iron, rarely before attempted upon such a great scale, but also in the planning and construction of the foundations and the masonry piers, particularly in those of the "Victoria" bridge, across the St. Lawrence, where special provision was necessary for resisting the pressure of the immense masses of floating ice set in motion on the breaking up of the frost at each spring. For the foundation of these piers and ice-breakers, Mr. Hodges, the engineer of the contractors, devised a most ingenious system of moveable coffer-dams, which answered admirably, and to him, as to Sir Morton Peto, M.P., Mr. Brassey, and Mr. E. L. Betts, the enterprizing contractors for the works, the utmost credit is due for the successful manner in which the great difficulties were met and overcome, and for the general successful result of their work. It is not necessary to describe these great works in detail, as this has already been done in the masterly and elaborate description of the Conway and Britannia bridges by Mr. Edwin Clark, and Messrs. Peto and Betts, and Mr. Hodges in the description of the "Victoria" bridge; to which works, those who take an especial interest in these important subjects are more particularly referred.

To Mr. G. R. Stephenson, as the representative of his cousin, the late Mr. Robert Stephenson, M.P., F.R.S., has been awarded a medal for the extraordinary boldness of conception and the great ingenuity of the construction; and to Sir S. Morton Peto, Bart., M.P., Mr. T. Brassey, Mr. E. L. Betts, and Mr. J. Hodges, a collective honourable mention, for the successful execution of this bridge, and for the ingenuity displayed by Mr. Hodges in the construction of the coffer-dams.

Next, and scarcely inferior in importance to the above-mentioned bridges, may be mentioned the bridge across the Wye, at Chepstow, and the "Albert" bridge over the Tamar, at Saltash, both designed by, and constructed under the direction of, the late Isambard Kingdom Brunel. These are of a somewhat different character, being a combination of a wrought-iron superstructure with cast-iron columns, the arrangement being upon the insistent and the suspension principles combined.

It may be a question whether one of these systems, particularly the insistent principle alone, if properly applied, of the requisite dimensions, would not have been as efficient, simpler, and better calculated to have answered the object in view: nevertheless, these two bridges have been extremely well designed and constructed, and they practically fulfil their object most successfully. The foundation of the great central, or deep-water pier, in the Tamar, for the Saltash bridge, was a most difficult and hazardous undertaking, as it was necessary to carry it down through a depth of water of 82 ft. at high water, with a rise of 18 ft. of tide. This foundation was carried down through a bed of soft mud, nearly 16 ft. thick, to the solid rock, which was effected by means of a wrought-iron cylinder of 37 ft. diameter and 90 ft. in height, which was forced down to the bottom partly by insistent weight, and partly by means of atmospheric pressure. The proceedings were so well arranged that little hazard was incurred, and the works of sinking the cylinder, constructing the masonry foundation, erecting the iron columns upon it, and lifting the tubes, were most successfully accomplished. In connection with the execution of this work, Mr. Brereton, the chief assistant of Mr. Brunel, should be mentioned as having carried out the views of the engineer most efficiently. To Mr. Isambard Brunel, as the representative of his father, the late Mr. I. K. Brunel, F.R.S. (United Kingdom, 2,245), has been awarded a medal, for the boldness of design and for ingenuity and goodness of construction and for the novel and excellent method of sinking the foundations of both these bridges.

The next work of this class is the lattice bridge across the river Boyne, at Drogheda, on the line of the Dublin and Belfast Railway. It was designed by and constructed under the direction of Sir John Macneill. It is upon the lattice principle of wrought iron, and is by far the largest structure of the kind which has hitherto been erected in the United Kingdom. The invention, or rather the first great application of this class of bridge, may be said to have taken its origin in the United States of America, where such structures of timber have been employed to a great extent. The merit of their introduction to Great Britain in the form of wrought iron may be attributed to Sir John Macneill, and they are now largely employed on the Continent and indeed all over the world. They come under the class of girder bridges, and the chief merit may be said to consist in the lightness and economy, consistent with a proper degree of strength. The bridge over the Boyne above mentioned, as well as another upon the same principle across one of the public streets at Dublin, upon the same line of railway, are extremely well designed and constructed, and are excellent examples of the kind, and as such are entitled to a considerable degree of credit.

To Sir J. Macneil, F.R.S. (United Kingdom, 2,316), has been awarded a medal for the importance of the design and the successful execution of this bridge; in which he received very efficient co-operation from James Barton, resident engineer.

Several large bridges upon the same principle have been designed by, and constructed for, Lieut.-Col. Kennedy, upon the line of the Bombay and Baroda Railway, India. The piers of these bridges are formed by means of Mitchell's cast-iron screw piles, firmly fixed in the bed of the river, and properly braced together by wrought-iron ties. These structures have not any pretensions to originality, but they are remakable for the simplicity and economy of their construction, for their successful completion, and for their completely answering the object for which they are intended. To Lieutenant-Colonel Kennedy (United Kingdom, 2,307) has been awarded a medal for the extensive application of screw-piles to bridges in India.

To Messrs. Gilkes, Wilson, and Co. (United Kingdom, 2,290), has also been awarded a medal for the excellence of execution of the iron railway viaduct, with cast-iron diagonally braced piers, erected by them over the river Belah, from the designs and under the direction of Mr. Bouch.

In connection with this branch of engineering, a medal has been awarded to Mr. E. C. E. Dapples, of Lausanne (Switzerland, 127), for an ingenious modification of the screw-pile shoes for timber or iron piles.

Next must be mentioned the bridges, models of which are exhibited (under the No. 1,251, in the French Catalogue) by the Minister of Agriculture, Commerce, and Public Works of France, whose liberality in collecting and transmitting to this country so excellent a collection of models of interesting works cannot be too highly eulogized. Many of these bridges are remarkable for the ingenuity and boldness of their design, and for the very successful manner in which they have been carried into effect.

First amongst these may be mentioned the great Turning Balanced Bridge across the Penfeld, a creek connected with the naval arsenal of Brest; this structure is by far the largest of the kind that has ever been attempted, and as such requires particular notice. It is composed wholly of wrought iron, with the exception of the counter-balance weights, which are of cast iron. The total width of the opening, or clear space between the two circular piers, or abutments on the opposite shores, is 106 metres. The bridge itself consists of two equal portions, which meet in the centre, at an elevation of 19½ metres above the level of high tide, each being supported on either side by a massive circular tower of granite masonry, upon which they revolve on a series of cast iron rollers, in a massive iron frame, which is made to rotate by means of a system of wheel-work, worked from the top by two men for each half, by whom, in calm weather, the operation of opening and shutting the bridge is performed in about fifteen minutes.

When the bridge is closed it is fixed in its place by means of self-acting keys, which are easily detached when it is required to open it for the passage of full-sized vessels.

The total width of the roadway, including that for the carriages as well as for the foot passengers, is 7½ metres.

The ends between the piers and the abutments, at the adjoining streets, are filled with the counter-balance weights, which are so regulated as to balance the other two and longer portions, between the piers and the centre of the opening, so perfectly as to enable the rotation to be effected with the least possible friction; and in order to afford ready access for repairs to the rollers, arrangements are made for lifting the entire ring, by hydraulic pressure, within a few minutes.

This bridge may be said to fulfil its purpose admirably, and whilst it forms a convenient and much required communication between the towns

of Brest and Récouvrance, which are situated on either side, it affords free passage for vessels of war under and through it, in consequence of its great height from the surface of high-water to the under-side of the arch.

The original project for this great work is due to Messrs. Cadiat and Oudry, to whom a collective medal has been awarded as the authors of the original project, and for its boldness and unique character; but the actual structure was designed and constructed by M. Mathieu, the able engineer of the Creusot Iron Works, and by Messrs. Schneider and Co., who were the contractors for the work. The erection of the structure was superintended by Messrs. Maitrot de Varennes and Aumaitre, engineers-in-chief of bridges and roads, and M. Rousseau, engineer.*

The next bridge most worthy of remark is that erected over the valley of the Sarine, on the line of the Fribourg and Lausanne Railway. It was designed and constructed by M. Mathieu, the engineer for the Creusot Company, who were the contractors for the work, and at whose establishment it was all manufactured.

The total length of this bridge is nearly 329 metres, and it consists of seven openings, of nearly 49 metres each, supported upon six cast-iron piers, composed of diagonal-framed panels, firmly braced together by wrought-iron rods placed diagonally. The openings are spanned by wrought-iron girders, upon the trellis principle; the highest pier in the deepest part of the valley being 80 metres in height, of which the upper length of 44 metres is in metal, so that in point of economy it became an object of the greatest importance to avoid the construction of scaffolding, which would have been attended with considerable expense; this was happily effected by a very ingenious and novel system. The lattice girders, with the platform forming the whole width of the bridge, were, in the first instance, constructed; or put together on one of the adjoining abutments, and placed upon rollers, over which they wers drawn forward until the end overhung the position at the first pier, having sufficient counterbalancing weights at the ends to prevent them from falling as they were moved onward. As a further precaution against this danger; the ends were stayed by chains and rods of wrought iron, attached to strong derricks, or cranes fixed upon the piers, provided with proper machinery for hauling them along, so that in proportion as they advanced the chains were shortened, until the ends of the girders reached the point over each pier. The panels for forming the pier were then brought forward upon the girders and platform, and were lowered to their position; so that the structure, in fact, grew up beneath the girders, which were then again drawn forward over the piers, and the same process was repeated until the whole bridge had been drawn across, when the platform was securely fixed in its position. By means of this novel, simple, and ingenious contrivance, this bold aud economical railway bridge, or viaduct, was most successfully constructed, to the great credit of the Creusot Iron Company and their able engineer-in-chief, M. Mathieu, inventor of the method of construction and builder of the bridge, to whom the Jury have awarded a medal, with the expression of their highest satisfaction for the invention and successful application of the method employed in the construction; and they thought it right to give an honourable mention to M. Clerc, for the excellence of the model of the bridge, exhibiting the mode of construction.

A road bridge, called the "Pont de St. Just," across the mountain torrent, the Ardeche, upon the same principle, with stone piers, was designed originally by M. Oudry, and constructed by the Creusot Iron Company, under the immediate direction of M. Mathieu, with equal success. This bridge, which consists of six spans of 46·26 metres each, was also remarkable for the obstacles encountered, not only in constructing the piers, in consequence of the extreme violence of the torrent during floods, but because it was absolutely necessary to provide a means of placing the wrought iron arched girders, without having recourse to the ordinary mode of fixing scaffolding beneath. This was accomplished by having a counterbalanced scaffolding, which was propelled forward from the abutment over the piers consecutively, having on it the means of raising the arched iron girders to their places on the piers. This was very successfully accomplished, without accident; and the award of a medal would be justly due to M. Mathieu, the engineer-in-chief of the Creusot works, to whom were entrusted all the details of the construction of this work, if he had not gained one for the bridge of Fribourg.

The next viaduct bridge worthy of remark is that over the Rhine, at Kehl, for connecting the Eastern Railway of France with the German system of railways at Strasbourg.

The execution of this great work was, by mutual consent, apportioned between the engineers of the Eastern Railway, who undertook the construction of the foundations and the piers, and the engineers of the Grand Duchy of Baden, who were charged with the execution and fixing of the superstructure. The foundations and the mode of executing them were designed and executed by M. Vuigner, engineer-in-chief, and Monsieur Fleur-Saint-Denis, resident engineer, with M. de Sappel, acting engineer; and their designs were carried into effect with great intelligence by the enterprising contractors, Messrs. Castor.

The general features of this viaduct are, masonry piers, supporting a superstructure of wrought-iron girders, on the trellis principle, with a lifting, opening at each extremity, to permit the passage of the masted vessels which navigate the Rhine.

The principle difficulties in the construction of this bridge arose from the depth of the river, the rapidity of the current, and the shifting nature of the bed, which, being composed of loose gravel, was at times scoured away to the depth of many feet; so that no bridge could be rendered permanent, unless the foundations of the piers were carried down to a depth below the action of the current. In order to effect this it was necessary to resort to extraordinary measures. This was effected by the employment of large wrought-iron caissons, placed side by side, so as to cover the entire space of the pier. These contained air cylinders, with valves in them rising from the top of the caissons to above the level of the water, and a large cylinder, open at both ends, having its lower extremity descending below the edges of the caisson. Within this latter cylinder was fixed a dredging frame and buckets.

To be continued.

* It would have been proposed to award a medal to M. Mathieu for this important work, but it was reserved for the design and execution of the Bridge of Fribourg, which are scarcely, if at all, less ingenious and successful than those of the Bridge of Brest.

NEW REGULATOR FOR TEMPERATURES.

A committee of the French Academy of Sciences reports very favourably of a new automatic temperature regulator which M. Eugene Rollaud has attached to his mechanical roaster, and which, the committee say, has worked for eight years with the precision of a piece of physical apparatus and the certainty of a practical machine. The combustion of the furnace is regulated by balance valves on the pipes through which the air is introduced, which valves are automatically governed by the regulator. This regulator consists of a mercury gauge, the closed branch of which is attached to a fixed support, while the cistern is freely suspended to the beam of a balance; the varying weight in this branch will cause the beam to assume different positions depending on the temperature of the apparatus, which variation of position may be used to govern the valve. In order to prevent the barometric changes from affecting the apparatus, the closed end of a syphon barometer, the tube of which is of the same diameter with the gauge, is attached to the beam, while its cistern is sustained by the fixed support. The barometric changes will then affect these two instruments equally and in opposite directions, and will, consequently, have no effect on the position of the balance beam.—*Comptes Rendus of the Academy of Sciences.*

Legal Intelligence.

Court of Queen's Bench, Guildhall, Dec. 12.—Kottula v. Palmer and others.—Mr. Bovill, Q.C., Mr. Webster, Mr. Joseph Browne, Q.C., Mr. Macrory, Q.C., appeared for the plaintiff; Mr. Macavc, Q.C., Mr. Hindmarch, Q.O., and Mr. Aston, were for the defendants.—This was for an action by the assignee of Messrs. Blake and Maxwell's patent for improvements in the manufacture of soap, dated August 30, 1856, against Messrs. Palmer and Co., the well-known patent candle and lamp makers.—After the time of the court had been occupied nearly two days, some witnesses for the defendant proved that soap, precisely the same as that, the making of which was alleged to be an infringement of the plaintiff's patent rights, had been made from a recipe in Kurten's book upon the subject before 1856, and soon after that work was known in England in 1853.—Mr. Bovill elected to be nonsuited.—The Lord Chief Justice said the case furnished another proof of the unsatisfactory state of the law as to patents.—Plaintiff nonsuited accordingly.

At a meeting of the Judicial Committee of Her Majesty's Privy Council, Whitehall, Saturday 15th of November, 1862—in the matter of the prolongation of Goucher's patent—the following judgment was delivered by Lord Justice Knight Bruce:—"Their Lordships are of opinion upon the evidence before them, that the invention now in question has been shown to be meritorious and beneficial, and subject to the observations and conditions to be presently mentioned; they are of opinion that there should be an extension of the term granted by the letters patent for three years from the time of its expiration. But their Lordships are not at present satisfied with the accounts, or with the evidence as to the amount of profit or loss that has followed from the invention, and they are desirous therefore, that the accounts, in an improved and extended state, if possible, should be laid before the Attorney General, if he will have the goodness, as probably he will, to undertake the matter, in order to satisfy him of what is a fair and correct view upon all the evidence which can reasonably be expected to be obtained of the amount of profit or loss from the invention. Their Lordships think that unless the amount of clear profit made by the invention shall be found to exceed £2,000, the extension already stated ought to take place, but, that if the clear profit shall be found to exceed £2,000, the extension ought not to take place. They do not think that, in calculating the amount of profit, the gains made by those who have had a license from the patentee, gains in which neither he nor the inspector, nor the mortgagee has participated, should be taken into account. In one possible view of the Statute Law upon the subject, it may be important that the opinion of the Attorney General upon the accounts should be given as speedily as it can be, if he will have the goodness to take charge of the matter. Their Lordships also think that there should be an undertaking on the part of the applicant to give the mortgagee and the inspector the same rights beneficially in the extended term as they now respectively have in the present letters patent."

At the annual general meeting of the Institute of Civil Engineers, on the 16th inst., Telford medals were presented to Sir Charles Augustus Hartley, Messrs. J. H. Muller, J. Paton, J. Abernethy, and J. Bailey Denton; a Watt medal to J. D'A. Samuda: a Stephenson prize of twenty-five guineas to Sir C. A. Hartley; Miller prizes, of fifteen guineas each, to J. H. Müller and J. Paton; council premiums of books to Capt. Douglas Galton, R.E., and Messrs. J. Brunlees, H. C. Forde, C.W. Siemens, J. A. Longridge, and J. Oldham; and the Manby premium, in books, to Sir C. A. Hartley. The following gentlemen were elected to fill the several offices of the council of the Institution of Civil Engineers for the ensuing year:—John Hawkshaw, president; J. Fowler, C. H. Gregory, J. R. McClean, and J. S. Russell, vice-presidents; Sir William Armstrong, N. Beardmore, J. Cubitt, T.E. Harrison, T. Hawksley, G. W. Hemans, J. Murray, G. R. Stephenson, C. Vignoles, and J. Whitworth, members; and J. T. Leather and F. Marrable, associates.

ANNULAR KILNS FOR BURNING BRICKS, LIME, EARTHENWARE, ETC., WITHOUT STOPPAGES.

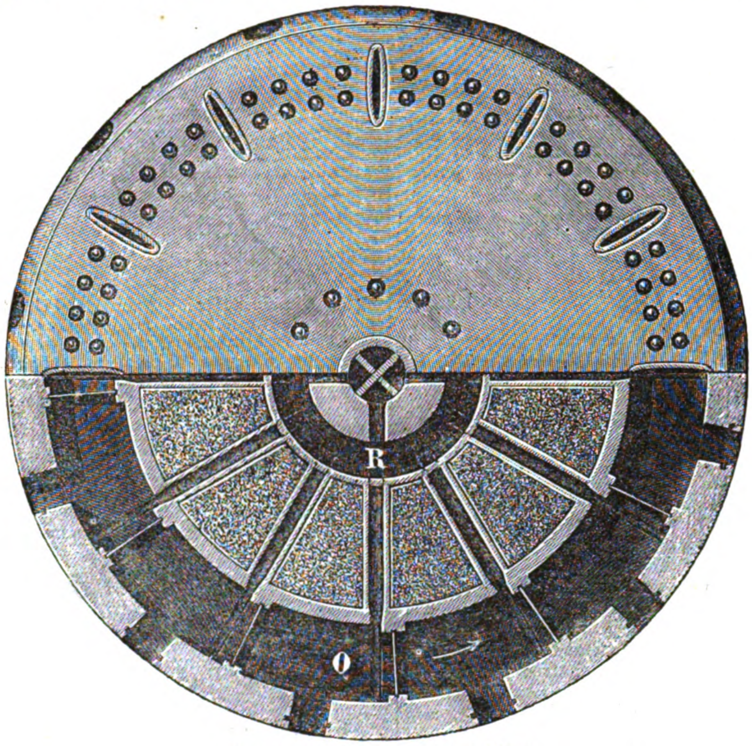


FIG. 1.—PLAN OF ANNULAR KILN.

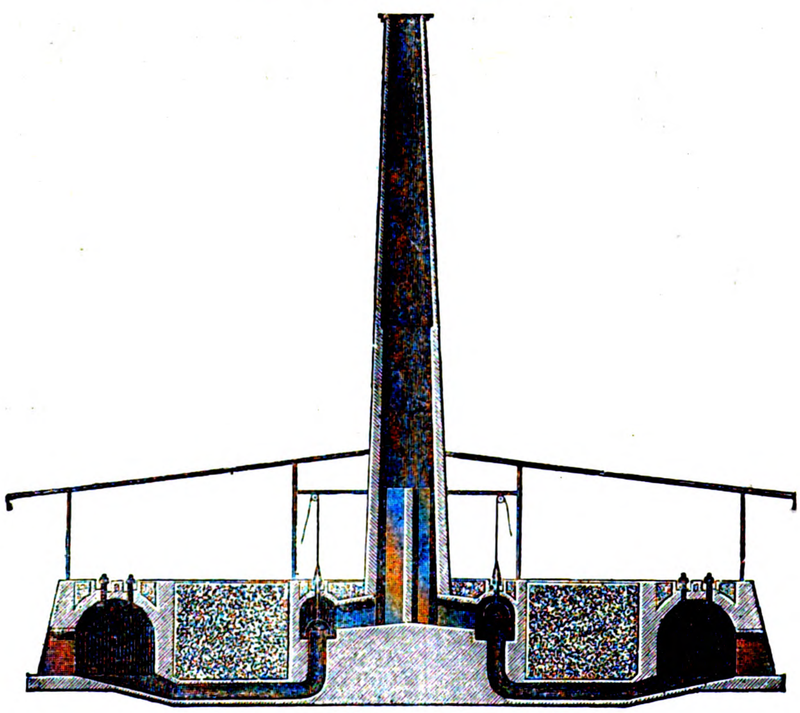

FIG. 2.—SECTIONAL ELEVATION OF ANNULAR KILN.

ANNULAR KILNS FOR BURNING BRICKS, LIME, EARTHENWARE, ETC., WITHOUT STOPPAGES.

IT is, of course, of great importance in the manufacturing of bricks, lime, pottery, &c., to reduce the consumption of fuel, and also to produce good articles in the shortest space of time. There exist already a great many improvements in the construction of furnaces, none of them, however, lead to very great economy, combined with simplicity in arrangement, together with the ready manipulation required. The Annular Furnaces of Messrs. Hoffman and Licht are said to work with much economy of fuel, saving in time, and the process of firing would not seem to require very skilled labour. This invention is, we believe, patented in Great Britain, France, Germany, and Belgium.

The annular form is adopted for these furnaces because it here affords the greatest strength. The furnace consists of a circular channel, O, of any section, which receives the articles to be fired, which articles are let in through doors in the outer wall, as shewn, or by apertures formed in the top of the arch. Flues, of the same number as the doors, lead from the bed of the furnace to the smoke chamber, R, which surrounds the base of the chimney stalk. The communication can be shut off when required by means of cast-iron bell-shaped covers. A damper, which is moveable along the furnace, can be lowered in grooves let into the walls of the furnace, immediately after each flue, so as to separate the horizontal section of the furnace into distinct and equi-distant compartments. The fuel passes through apertures which are formed in the top of the arch—thence through channels, which are formed by the objects to be burned, to the bed of the furnace in which a certain number of flues are cut to produce a free current to the fire in all parts.

There may be, for instance, twelve entrances or doors—in consequence of which, there are the same number of flues communicating with the chimney stalk, and just as many slits in the arch for the reception of the plate damper. Thus the furnace may be divided into twelve parts. For a better distinction, these compartments may be numbered from one to twelve, of which two, No. 12 and No. 1, are separated by the damper.

FIG. 3.—DIAGRAM SHOWING MANIPULATION.

The objects supposed to be burned may be bricks or tiles, and the fire in full operation; the doors leading to the compartments 1 and 2 being open—No. 1 for filling them with fresh bricks, and No. 2 for taking out the burned bricks. The compartments, Nos. 3, 4, 5, and 6, which are all filled with burned bricks, being gradually cooled by the air entering through the doors of No. 1 and 2, and passing over warmer and at last glowing bricks, it will result that the fire is supplied with atmospheric air almost as hot as the furnace itself. In the compartment, No. 7, is the burning fire; and when its contents are ready burned, the contents of No. 8 will already be heated to such a degree that the fuel introduced from the top is instantaneously inflamed. The compartments, Nos. 9, 10, and 11, will be heated one after another by the hot air which passes and imparts the heat to the contents of these compartments, and then rushes into the last compartment, No. 12; the air is then caused to escape through the open flue into the chimney by pushing down the damper. No. 1 is then filled again, the damper between 12 and 1 is lifted and lowered between 1 and 2. The bell above the mouth of the flue No. 12 must be lowered, and that of No. 1 lifted. The opening *b* of No. 12 must then be closed, and that of the compartment No. 3 opened; the contents of which will be sufficiently cooled to be taken out, while No. 2, which is empty, can be filled again. It is thus possible to burn bricks or lime, and to fill or empty the furnaces at the same time, and without interruption.

The advantages claimed for the arrangements described, as compared with the old plan, are as follow:—The atmospheric air necessary for the support of the fire absorbs the heat of the ready burned bricks, and supplies the fire of the furnace with hot air. On the other side the superfluous heat contributes to the gradual heating of the bricks to be burned, so that no heat is lost except that in the hot air necessary for keeping up the draught in the chimney-stalk. The furnace and walls are coated with non-conducting material, and the whole structure is insulated by plates of asphalte under the foundation, by which means the escape of heat is reduced as much as possible. The apertures through which the furnace receives the combustibles are in consecutive communication with each other, so that at any time the state and progress of the fire in the furnace can be examined and regulated. The charg-

EMERY'S AMERICAN THRASHING MACHINE.—(*See page 395.*)

(*See page 395.*)

FIG. 1.

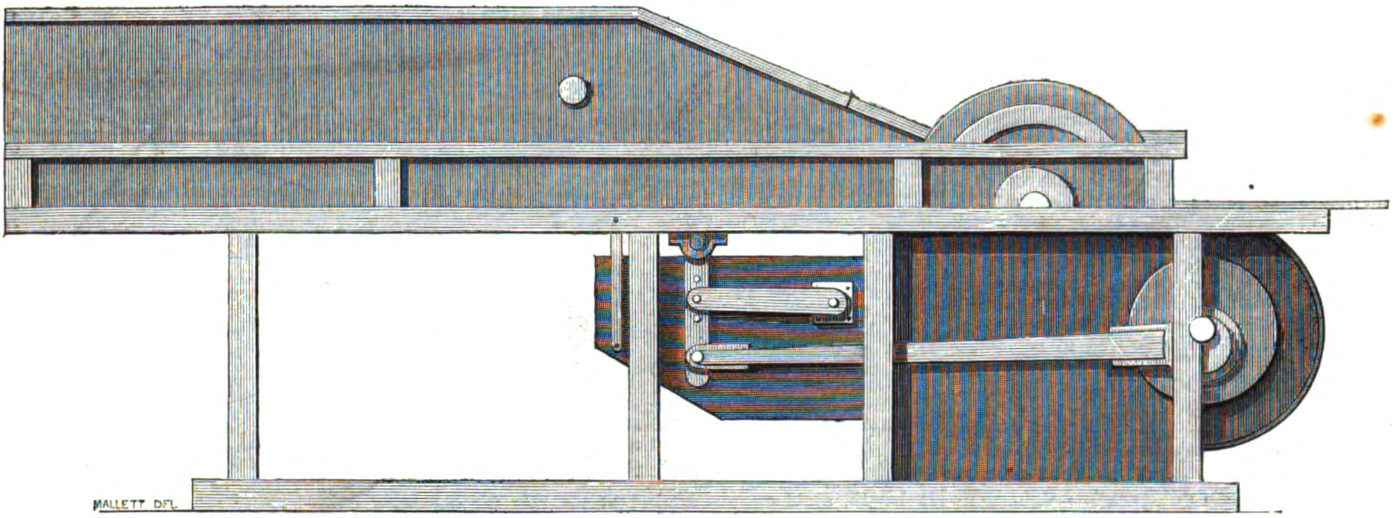

FIG. 2.

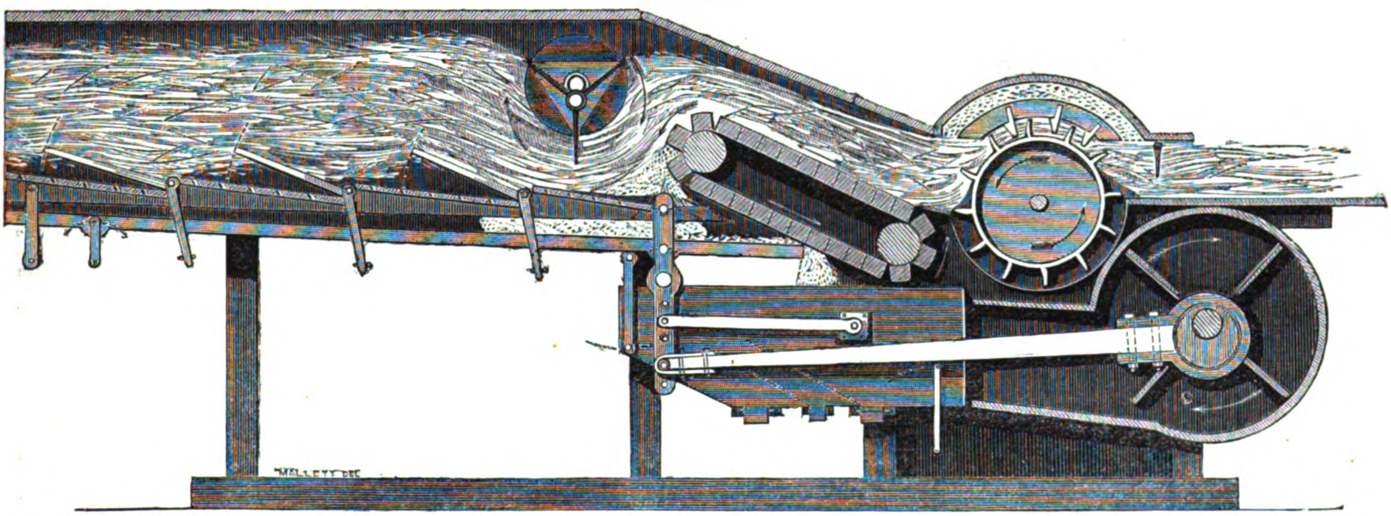

ing and emptying of the furnace can be done at the same time, and without interruption, and it is not necessary to wait for the bricks to cool. A saving is also effected in building the furnaces as compared with those of the old construction. For the production of the same large quantity of bricks in the old kilns, it would necessitate a number of furnaces being employed. The height of the furnace scarcely exceeds that which a man can reach with his hands, and thus greatly facilitates the putting in and taking out of the articles to be burned. The compartments of the furnace are constantly emptying in succession, and the repairs can thus be done without stopping the whole furnace. As the combustibles are thrown into compartments already very hot, any inferior sort of fuel can be used. The furnace seems to be adapted for burning lime, cement, and firing pottery-ware as well as bricks, because the draft can be regulated and the heat thereby increased or diminished.

The cost of these brick kilns varies between £500 and £2000, according to size and local circumstances. We have seen testimonials shewing that these furnaces are at work at several places in Germany.

CAPTAIN JOHN HARVEY.—A short account of Navez's Electro-Ballistic apparatus (the machine in use at Shoeburyness, for determining the initial and impact velocities of projectiles), is to be found in the "Lectures on Artillery," by Major Owen and Captain Dames. It was also briefly described in our number for Dec. 5.

THE BATH SCHOOL OF ART.

ON the 26th ult., the annual distribution of the prizes, in connection with the Bath School of Art, took place at the Guildhall, in that town.

The Rev. E. D. RHODES, in opening the meeting, gave a very interesting and instructive address upon the progress of the society, and the importance of similar schools generally. He especially advocated the connection of

BEAUTY AND USEFULNESS

in all buildings. He believed it was Smeaton who had to construct the Eddystone Lighthouse at Plymouth, and his attention was directed by his scientific training, not by the artistic training which he had received to the stem of a tree. It struck him, "Now this tree—this creature that I am looking at there, has a tremendous strain upon this pillar which supports that large amount of branches above, and those branches are swayed by the force and violence of the winds, so that there must be, as any architect would observe, some peculiar fitness in the form of the pillar to support, not merely the incumbent weight which is always pressing upon it, but also the extraordinary strain which the storm and tempest engender. I want to erect a building something after the character of this stem—an upright, tall, slender building, proportionable, which is to encounter the storms, and tempests, and violence that assails this tree. Would it not be wise to copy the stem of the tree in the building I am going to erect, that peculiar curve which the stem takes from the ground up to the point of ramification; that gradation and that gentle diminution?" Smeaton did so, and built the Eddystone Lighthouse upon that principle. Storm and tempest had assailed it with as much severity as anything that had been there before, but although other buildings of a similar kind erected there had been overthrown one after another, Smeaton's structure still stood untouched and unhurt. Now here was an instance, they would say, of the perfectness of contrivance of infinite wisdom, which adapted all forms of creation to the ends of creation; but was there not also an instance of beauty? Look at the stem of a tree and conceive, if they could, any form that supported a head above it more beautiful than that—conceive any tapering form more exquisitely contrived and more gradually diminished upon a principle of curvature, more perfect, scientifically, as well as artistically. It presented to them a strong instance of how beauty was connected with use. He would give them another instance. There could be little doubt that in sculpture, at least, the form of the human head was as beautiful a thing in its place as could possibly be conceived. We need only take the skull of the gorilla, or of any other animal in existence, and put it upon the human neck, and they would see how vastly the human form had lost in beauty by that change in the form of the skull. Here, then, was another model of beauty. He believed it was a fact upon record that when either Sir Christopher Wren or Michael Angelo (he thought the former) had to build the dome of St. Paul's, or if Michael An-

gelo, the dome of St. Peter's, it occurred to him that there could be no domed form more adapted to strength in proportion to material than that of the human skull; that the evident necessities of the skull of the head would be, that it should have as much strength as could possibly be commanded with the necessary lightness; that the material which formed the bony structure of the skull should be so arranged as to combine the greatest possible strength for the purpose intended, which was to preserve the life of man; and accordingly that the curvature of the dome should be such as would offer the greatest resistance to any violence or any pressure from without, and which should endure the greatest weight which could be borne upon such a texture. In short, that the form of the dome of the skull was the most serviceable and the most useful to adopt, and the thing was proved to be mathematically true.

The prizes were distributed, and several votes of thanks carried.

TO CORRESPONDENTS.

RECEIVED.—W. A.; the papers are returned by post; R.N., P. Le N.F., J.S.P., J.H.D., R.P., J.H.P., W.W., Capt. B.

STEAM PLOUGHING.

TO THE EDITOR OF THE "MECHANICS' MAGAZINE."

SIR,—Allow me a word on your remark "Messrs. Howard seem to have improved Mr. Smith's invention off the face of creation," in your article on the Smithfield Club Show. If my not exhibiting my inventions in the newly created Hall can prove the point, it may be true; but it is not so; for I have 188 customers who are working them most successfully. Here is a brief history of the working of one set.

Mr. Pike, of Stevington, Beds, bought a set in May, 1858, and worked it on his heavy clay farm down to the spring of 1861, and, according to his own showing, did over 2,000 acres with it. He then adopted what is called Howard's improvements, and sold his set of mine to Mr. Hutchinson, of Manthorpe Lodge, Grantham, who worked it upon the Dunton Lodge Farm, near Biggleswade, a very heavy clay farm, from the spring of 1861 to now, and, according to his own showing, did, in 1861, 751 acres in 133 days, averaging 5a. 2r. 23p. per day, at a cost of 4s. 6d. per acre, exclusive of wear and tear, and in 1862, 775 acres in 131½ days, averaging 5a. 3r. 23p. per day, at a cost of 6s. 2d. per acre, inclusive of wear and tear, with interest &c. The set of tackle is now reported to be, in appearance, as good as when it was first worked at Dunton Lodge, and Mr. Pike wrote on Dec. 31, 1860, that it was very little the worse for wear.

Surely this does not show that my inventions are improved out of creation. The fact is, the evidence is daily strengthening on these sides, and it may be that they will outlive the said to be improved tackle of both Mr. Fowler and Mr. Howard, neither of which can show land cultivated and planted at one operation by their inventions, although I can, and at a cost of only 6s. per acre, inclusive of wear and tear.

I am, &c.,
WILLIAM SMITH.

Woolston, Bletchley Station, Bucks,
Dec. 13, 1862.

THE ATLANTIC TELEGRAPH COMPANY'S SCHEME.

SIR,—In ordinary enterprizes it is a matter of little public moment whether men part with their money wisely or foolishly. In the one case they will receive the congratulations of their friends for their success, and will be able to contemplate with satisfaction an increase in their means of enjoying life; in the latter they will be laughed at for their folly, and must bear the loss of their money with the best grace they can; but the public, generally speaking, are in no way interested in the result. Not so, however, when the failure may prevent the realization of a great boon to the whole world, such as must be derived by telegraphic communication between Europe and America. It is for this reason I have ventured to make some reflections with respect to the present attempt of the old Atlantic Company to resuscitate their enterprize. If they fail, the result would be a death blow to the well-grounded hopes of success, which other routes claim to have upon public support.

The Atlantic Telegraph Company have announced their intention of inviting the public to lay out £600,000 of new capital, the nett proceeds of which, should they be fortunate in laying the cables, they estimate at £413,000 per annum, producing 18 per cent. upon the new capital, 14 per cent. upon the £402,860 of old capital previously expended, and leaving after all a balance for reserve fund of £240,200 per annum! The rate of working upon which this estimate is based appears to have been derived from the united experience acquired upon two short shoal-water cables in the North Sea, and is altogether at variance with the opinion of the* first electricians of the day, and with the laws derived from the actual working results of longer lines, which show that the speed of signalling is reduced inversely as the square of the length of the cable. Hence it was that the line formerly laid between Newfoundland and Ireland, 2,200 miles in length, could only be worked at the rate of about a word a minute; and for the same reason the Government recently, in laying the Malta and Alexandria cable, divided the length into three sections, intermediate stations being opened at Bengazi and Tripoli, not (as the Atlantic Telegraph Company have the hardihood to maintain) for the sake of the few pounds of annual traffic to be got then, but to enable the line to be worked through at a commercially paying rate, which could not be effected with the slow speed of working through the entire length of the line in one circuit. This is one of the greatest objections to the long route, and the company seem not altogether ignorant of it themselves; for, although they estimate their traffic so liberally, they state that their preference shares are to be guaranteed 8 per cent. dividend from the Government "in the event of success." It would appear from this, that if the line, being once laid, could only convey a message per day, the Government would have to pay the working expenses of £25,000 a year, and £48,000 dividend on the preference shares. The estimate of receipts to which I have referred is calculated by the company upon an uninterrupted rate of working of 10 words per minute for 16 hours out of 24, or 480 messages a day, which is assumed to be a moderate expectation, because 1,500 messages are said to be passed daily between this country and the Continent. It must be remembered, however, that the Continental traffic spoken of is spread over no less than 35 conducting wires, none of which are so long as to be materially subject to the retardation and confusion of signals by inductive phenomena, which are so prejudicial to the well-working of lines of great length. When the Government are applied to for assistance in the construction of a line of telegraph to America, which will no doubt be the case before long, as no less than three distinct undertakings are in the field, it is most earnestly to be hoped, in the interests of the public, that the whole matter will be referred to a competent committee to investigate. It will then be determined whether the direct line, with its enormous large stretch in one single risk, and its great electrical obstacles, affords the best promise of success, and is most worthy of aid from the public purse; or whether the several other routes in shorter sections by the Northern or Icelandic route, by the Azores, by the Canary and Cape Verde Islands and Brazil, or by the Aleutian Islands and British Columbia, are not, any or all of them immeasurably superior to the line between Ireland and Newfoundland?

I am, &c.,
GEOGRAPHER.

London, Dec. 11, 1862.

* Why did our correspondent not specify the authorities?

SIR,—There are two errata in the letter which I addressed to you in the last week's number of your MAGAZINE, which, if not corrected, your readers could make any sense of the sentence in which it is placed; for "cotter" read "latter," and for "screw" read "screen."

Having corrected the mistakes, I covet a small space in your MAGAZINE to offer some further remarks about the fin.

In reconsidering what I had stated, that its greatest turning power would be obtained by placing it the fore part of a ship instead of the after part, I still adhere to that point; but I have since reflected how much inferior the turning power of a fin is to that of a fore rudder hinged on the stem of a ship, which I shall endeavour to explain:—1, Its longer leverage from the fulcrum of the ship's turning. 2, That it is now well known that the velocity of fluids acts upon the fore part of plane surfaces (whose pivots are central) with greater force than on the after part, when placed at any other angle than that of a right one, so that a fore rudder would be superior in turning power than an after one, the areas of both being equal. 3, Suppose the fore rudder to be put over to starboard (the helm, of course, to port), it would act as a screen, cutting off the stream, which would otherwise impinge itself upon the starboard bow of the ship, whilst the port bow would be acted upon by the full force of the stream, thus giving its aid to the turning power of the rudder; for if, by *imagination*, a force be supposed to act upon the port bow of a ship, whilst none existed on the opposite one, why a ship would turn without any rudder whatever. On the other hand, a fin, when put over on the starboard side, would screen the current which would otherwise be acting on the starboard bow of the ship, and thus the power of the fin would be diminished, instead of being aided, as in the case of the fore rudder. I do not here discuss how the fore rudder is to be managed or worked, that being quite another affair. But as I have learnt that my Lords of the Admiralty have ordered experiments to be tried on ships fitted with two rudders, it may be useful, by way of arriving at some glimpse of truth by theory, before it ends in practical disappointment.

I am, &c.,
MOLYNEUX SHULDHAM,
Comm. R.N.

21, Wellington-villas, Brighton,
16th Dec., 1862.

SIR,—In your number of December 12th, you were good enough to answer, by an extract from the *Journal of the Franklin Institution*, a question of mine concerning the penetration of projectiles into iron, but as my note did not convey to you the exact purport which I had intended, I venture again to trouble you on the same subject. In the dissertation on "Vis Viva," from the *Journal of the Franklin Institution*, it is *assumed* that in impact "*the amount of compression is directly proportioned to the square of the velocities.*" If this were so with all natures of bodies, penetration would, of course, be proportionate, or nearly so, to V^2. But experiment has shown that the penetration into some substances does not vary as V^2. Very few investigations into the theory and practice of penetration are known to the public; but experiments made by Dr. Hutton, and in France, showed that the penetration of projectiles into wood, into earth, and into masonry, instead of varying with V^2, vary nearly as the logarithm of V^2. This being so, you will, I think, allow that there is reason to doubt the correctness of the $W V^2$ theory, as it concerns penetration into iron, until facts are advanced to prove that for this material it holds good.

The $W V^2$ theory can be correct only if the resistance to penetration is a constant force. Adopting ordinary mathematical notation, if R be the resistance to penetration of a projectile moving with velocity V, by calculus

$$f = -R : f\ v\frac{dv}{dx} = -R \therefore v\,dv = -R\,dx$$

$$\text{Integrating } \frac{v^2}{2} = -Rx + C;\ \text{If } x = 0,\ v = V.$$

$$\frac{V^2 - v^2}{2} = Rx,\ \text{if } v = o,\ x = \text{total penetration}$$

$$x = \frac{V^2}{2R},\ \text{or } x \text{ is proportional to } V^2,$$

but this is only the case when R is a constant force. The question then that naturally follows: "*Is* the resistance to penetration a constant force" in the case of iron? How has it been ascertained that it is so? By experiments showing that penetration varies as $W V^2$? or by independent reasoning and experiment on the molecular resistance of iron? Could you inform me if any experiments have been undertaken to elucidate the theory, and if any work or treatise has been published on this particular subject.

I am, &c.,
IRON.

Dec. 13, 1862.

Strong brown paper is now manufactured at the Salisbury Paper Mills, in Orange county, from "cat tails," the product of the wild flag growing in low grounds all over the North.

FRI. — *Architectural Assoc.*, Prize Essays.
SAT. — *Royal Inst.*, "On Air and Water" (juvenile lecture), by Professor Frankland, F.R.S., at 3 p.m.

Gossip.

Elias Howe, jun., the inventor of the sewing machine, carries the daily mail from Washington to the camp of the 17th Connecticut Regiment, in which he is a private.

CUT OFF THE BACK LEGS OF YOUR CHAIRS.—I will tell you a secret worth knowing. A thousand things not worth half as much have been patented and elevated into a business. It is this: If you cut off the back legs of your chairs, so that the back part of the seat shall be two inches lower than the front part, it will greatly relieve the fatigue of sitting, and keep your spine in better shape. The principal fatigue in sitting comes from your sliding forward, and thus straining the ligaments and muscles in the small of the back. The expedient I have advised will obviate this tendency, and, as I have suggested, add greatly to the comfort and healthfulness of the sittting posture. The front edge of a chair should not be more than fifteen inches high for the average man, nor more than fourteen for the average woman. The average chair is now seventeen inches high, for all, which no amount of slanting in the seat can make comfortable. *Lewis's Gymnasium.*

WIRE-ROPES.—An invention has been patented by Mr. Geo. Bedson, of Manchester, which consists in the employment of flat wire in the manufacture of wire-rope. In preparing wire for ropes he causes it after it passes hot from rollers to be wound on a drum, thus affording two points of suspension, between which he cools it, and so causes a contraction, by which the material becomes straightened.

NATIONAL EXHIBITION IN TURKEY.—We have received from the Ottoman Embassy the following notification:—A National Exhibition is to be opened at Constantinople on the 1st Ramazan (20th Feb., 1863), for three months. Although reserved exclusively for the products of the soil and industry of the country, nevertheless agricultural and industrial machines and implements, for practical use, from foreign manufactories, will be admitted. Manufacturers wishing to exhibit such articles will enjoy the benefit of a remission of the customs duties. It is well understood that the admission of foreign products will be limited to this sole category, and that a manufacturer cannot send more than one article of the same kind. Exhibitors must, in the first place, send to the Imperial Ottoman Embassy, or to a Consulate of the Sublime Porte, a duplicate list of the articles they wish to exhibit, stating the quality, quantity, and necessary dimensions, so that places may be reserved for them. The articles above-mentioned which, after having been exhibited, shall not have been sold on the exhibitor's account, will not enjoy any other advantage on the part of the Imperial Government than the exemption from customs duties.

GUN METAL.—A correspondent of *The Times* says:—As the public is now much interested in gunnery, and as a short statement on recent experiments in Austria on this important subject has just appeared in *The Times*, I have pleasure in communicating to you the composition and mode of forming the new alloy which has been proposed in that country as a substitute for ordinary gun-metal, consisting of copper and tin. It is composed of 60 parts of copper, from 34 to 44 of spelter, from two to four of iron, and from one to two of tin. The iron, which must be wrought iron, is put at the bottom of a crucible with the copper upon it, and the whole exposed to a very high temperature. The tin is then added, and afterwards the spelter. The metal is stirred, left for a minute or two, stirred again, and afterwards cast. A 12-pounder gun made of this alloy was heavily charged with powder, rammed full of sand, plugged at the muzzle with a piece of iron, and in this state fired. All the gas resulting from the ignition of the powder escaped through the touchhole; and not only was the gun found to be uninjured, but on careful examination not the smallest alteration in its internal diameter could be detected. This indicates extraordinary toughness and elasticity. The preceding information has been personally communicated to me by the inventor with full permission to disclose it. I do not know whether the alloy has been patented or not in this country. I have no doubt that the announcement of these details in your columns will soon induce competent persons to test their accuracy.

ORIGIN OF PETROLEUM.—The flow of oil from mineral springs is by no means new either to science or commerce. Herodotus has recorded that the island of Zante furnished large quantities, while Pliny and Dioscorides describe the oil obtained from Agrigentum, a small town in Sicily. The Persian springs at Bakoum have yielded to the value of 600,000 dols. annually; and the earth oil from Rangoon, in Burmah, has been exported to the extent of 400,000 hogsheads yearly. The streets of Genoa and Amiens were formerly lit by a petroleum obtained from Parma. In 1847, a spring was discovered in Yorkshtre, which was successfully worked by Mr. James Young, of Glasgow, until exhausted, when he turned his attention to the distillation of coal, and discovered paraffin oil. The marvellous oil springs of the New World, however, far surpass in extent and interest all previous discoveries, and the quantity already yielded, without apparently diminishing the supply, shows that this will be a most important article of commerce for some years to come. In Canada the oil rises from the saturated corniferous limestones; in the States it is principally obtained from Devonian sandstones, while in Western Virginia and Ohio it rises directly from the coal measures. In all cases it, no doubt, arises from the decomposition of coal by temperature and pressure, and is lifted by the percolation of water under it to cavities and fissures in rocks till it approaches the surface, and it is generally accompanied by quantities of coal gas.—*Dr. J. B. Edwards.*

The iron-clad steamer "Passaic" has at length reached her destination at Fortress Monroe. The buoyancy of the vessel is said to have been very good. Owing to the impossibility of making the usual arrangements to prevent water coming in at the junction of the turret with the deck, it was thought that much inconvenience would be felt from this cause. The ship answered her helm satisfactorily, but the present steering wheel will be removed to make room for a larger one. The deviation of the compass was about one quarter of a point.—*Scientific American.*

SINGULAR SHOT.—At the Navy Yard, a short time since, an experiment was made with a 10-inch Dahlgren (smooth-bore) gun. A solid shot, weighing 130 lb., was thrown at an iron-clad target, at a distance of 500 yards, perforating the iron plating, 4 in. thick, as also 10 in. oak planking, passing out on the other side. The plating was torn into fragments, one piece flying backward into the joiners' shop, 200 yards in the rear of the gun, and 700 from the target.—*National Intelligencer.*

WATERPROOF WALKS.—But a new method of path-making is fast coming into vogue, and will soon be universally adopted for its cheapness, general excellence, and permanence; in fact, when once well done, it lasts for ever. Instead of making the walk of loose material, on the old fashion, concreting is resorted to, by which the appearance of gravel is retained, with all its freshness and beauty of contrast to grass and flowers, and the walk itself is rendered as dry and durable as the best pavement. The *modus operandi* is as follows:—Procure a sufficient quantity of the best Portland cement, then with the help of a labourer turn up the path with a pick, and have all the old gravel screened, so as to separate the loam and surface weeds from it, and to every six parts of the gravel add three parts of gritty sand of any kind—but soft pit sand is unsuitable—and one part, by measure, of Portland cement. When these are well mixed together in a dry state, add sufficient water to make the whole into a moderately stiff working consistence, and lay it down quickly two inches thick on a hard bottom. A common spade is the best tool with which to spread it; it must be at once spread, as it is to remain for ever, and a slight convexity given to the surface. In 48 hours it becomes as hard as a rock; not a drop of rain will go through it; and if a drop lodges on it, blame yourself for not having made the surface even—but a very moderate fall is sufficient with such an impenetrable material. Not a weed will ever grow on a path so formed; not a worm will ever work through it; a birch broom will keep the surface clean and bright, and of course it never requires rolling. It is necessary to be very particular as to the quality of the cement, for a great deal of rubbish is sold under the name of real Portland. Those who find any difficulty in procuring the genuine thing should apply to Messrs. White, of Millbank, Westminster, who are extensive manufacturers of this and other similar preparations, and can in every way be depended upon. For the flooring of a greenhouse, fowl-house, potting-shed, or barn, this is the best and cheapest that can be had—always clean, hard, and dry, and never requiring repairs of any kind if carefully put down in the first instance.—*Gardener's Weekly Magazine and Floricultural Cabinet.*

SHOWING THE WAY TO DO IT.—On the first day of trial with the flat-headed steel bolt, slightly cupped in its face, after the manner of a steel punch, for piercing holes in boiler-plates, against the iron boiler-plate, three-eighths of an inch thick, the face of the bolt was upset or bulged out by the force of the impact, and the plate, in consequence, was only indented. Mr. Lecky, C.E. to the Cork and Bandon Railway, told me that the flat-fronted steel bolt only failed in perforating the boiler-plate because it was not sufficiently hardened by tempering. I had it and another hardened, accordingly, and the next day of trial both bolts perforated the boiler plate—one at forty yards distance, the other at sixty yards. Mr. Lecky further stated his belief, that, had the boiler-plate been even half-an-inch thick, the bolts would have perforated it.—*John Norton.*

THE NEW SCREW RAM.—A New York paper states that the "Dunderberg" is being built 378 ft. long, 68 broad, 32 deep, with engines of 6,000-horse power. The hull is built of wood, placed so as to form a solid mass. The decks, sides, and floor are solid, and of a great thickness, so much so that if the figures were given all would be greatly surprised at the amount of wood used in the construction. This enormous wooden hull is heavily plated with rolled iron plates, which cover the entire upper portion of the vessel, and extend six feet below the water line. The weight of this terrible armour is not far from 1,200 tons. The bow of the vessel, for 50 ft. abaft the stem, is of solid wood, with no space between the sides of the vessel, this being covered with iron, forming the most gigantic ram on record, having powers of resistance unequaled in every respect. The sides of this vessel, above the water line, are seven feet thick and of solid wood, added to which is the heavy iron plating. This vessel has two rudders, one at each end, so protected that should one become disabled from any cause, the other can be easily used. The engines will give this vessel a very high speed, so that when she strikes a vessel she would crush through her with perfect ease. Above the main deck the build is very peculiar, but at present cannot be described. In addition to a large casement, containing heavy broadside guns, there will be two of Ericsson's revolving turrets, each containng two 15-inch guns. The naval register puts her armament down at 10 guns, but it will be much larger. The accommodation of the officers and men are to be of a superior kind, large, airy, and as well ventilated as an ordinary ocean steamer, yet giving to them all the necesssary security in time of action. In every respect she will be one of the wonders of the age. She is intended more particularly for harbour defences, but can readily go to sea, as she possesses all the qualifications for buoyancy, &c. She wlll be a most terrible affair, and will defy anything else in the shape of an iron-clad. She is to be finished as soon as circumstances will permit.

THE FIRST ENGLISH STEAMER.—The "Margery" was built at Dumbarton, by the late Mr. W. Denny (father of the eminent firm of shipbuilders of that name, now also in Dumbarton), for Mr. W. Anderson, merchant, Glasgow, and when launched, was christened the "Margery," after his eldest daughter, who named her, and who is still alive, and at present a resident in London. At the close of the year 1814 Captain Curtis was sent by a London company to Glasgow, to negotiate with Mr. Anderson for the purchase of the "Margery," which was effected, the only stipulation made by Mr. Anderson being that the name of the steamer should at no future time be changed; this Captain Curtis agreed to, and the promise was faithfully kept. Captain Curtis took the "Margery" through the Forth and Clyde Canal, and invited a large party of Mr. Anderson's friends to accompany him while passing through the canal, and was most hospitable in his entertainment to them. There remain but two of this party now alive—viz., the lady, after whom the steamer was named, and a clergyman, a friend of Mr. Anderson's. The writer of the article in the *Dumbarton Herald* is quite correct as to his statements of the fear and wonder which the appearance of the "Margery" excited on the coast, while on her passage to England, as well as among the English fleet; in most cases she was supposed to be a vessel on fire. The "Margery" was the first steam-ship that ever sailed in English waters, and made her first trip to Milton, below Gravesend, on the 23rd January, 1815 (see *Journal of the So-*

ciety of Arts, for January 27, 1860). She was ultimately taken to Paris, where not many years ago her timbers were still lying on the banks of the Seine. Mr. Anderson was, therefore, owner of the first steamer that was ever seen in London, and also in Paris; he also owned the first that ever crossed from Scotland to Ireland (viz., the "Greenock," built soon after the "Margery"), which he took to Belfast; he also took the first to Londonderry—the "Princess Charlotte." The late Mr. Anderson was grandfather to the Messrs. Gwynne, engineers, of Essex-street wharves, whose large centrifugal pumping-engine in the International Exhibition attracted so much admiration and attention during the past season.

Wright's Tar-paving.—The many just complaints about the stone paving in the Inner Quadrangle of Somerset House, have at length been listened to. The whole of it has been taken up, and the square covered with Wright's tar-paving, which is said to have been used with success at Woolwich and other Government works. The finishing layer of this material will not be put down until the spring of next year. It will then be fairly open to public criticism, and we shall take the opportunity of describing the process of its manufacture, its advantages, and the effect of weather and continual traffic upon it.

Patents for Inventions.

ABRIDGED SPECIFICATIONS OF PATENTS.

The Abridged Specifications of Patents given below are classified, according to the subjects to which the respective inventions refer, in the following Table. By the system of classification adopted, the numerical and chronological order of the specifications is preserved, and combined with all the advantages of a division into classes. It should be understood that these abridgements are prepared exclusively for this Magazine from official copies supplied by the Government, and are therefore the property of the Proprietors of this Magazine. Other Papers are hereby warned not to produce them without an acknowledgement:—

Steam Engines, &c., 1514, 1568.
Boilers and Furnaces, 1502, 1528.
Roads and Vehicles, including railway plant and carriages, saddlery and harness, &c., 1519, 1537, 1539.
Ships and Boats, including their fittings, 1503, 1506, 1508, 1524, 1527, 1531, 1534, 1535, 1561.
Cultivation of the Soil, including agricultural implements and machines—*none*.
Food and Beverages, including apparatus for preparing food for men and animals, 1510, 1520.
Fibrous Fabrics, including machinery for treating fibres, pulp, paper, &c., 1499, 1501, 1509, 1513, 1529, 1538, 1554, 1555, 1556, 1559, 1560, 1565, 1566.
Buildings and Building Materials, 1512.
Lighting, Heating, and Ventilating, 1523, 1564.
Furniture and Apparel, including household utensils, time-keepers, jewellery, musical instruments, &c., 1504, 1522, 1526, 1530, 1536, 1543, 1545, 1548, 1563.
Metals, including apparatus for their manufacture, 1521, 1558.
Chemistry and Photography—*none*.
Electrical Apparatus, 1515, 1516, 1540, 1541, 1549, 1550.
Warfare, 1518, 1544, 1546, 1553.
Letter-Press Printing—*none*.
Miscellaneous, 1500, 1507, 1511, 1517, 1525, 1533, 1542, 1547, 1551, 1552, 1557, 1562, 1567.

1499. E. Tailbonis. *Improvements in rectilinear knitting frames.* Dated May 17, 1862.

This consists in applying to rectilinear knitting frames a mechanical arrangement, by which the inventor obtains the required diminutions by the same power as that for working the loom without hand work. The supporting bars are placed under the needles at the taking-up place to form the meshes with regularity even with uneven or stiff threads. By the improved arrangement he has the shaft which carries the cams eccentrics, and inclined planes, longer than usual, so that, by a peculiar mechanical arrangement, the shaft is enabled to receive a lateral motion, which causes it to slide in the bearings; the different parts carried by the shaft then act on the spherical agents by which the diminution is effected on each side of the different pieces of knitted fabric, the weaver only having to take care that the threads do not break. *Patent abandoned.*

1500. J. Hogg, jun. *Improvements in book-covers.* Dated May 17, 1862.

The main feature of this invention consists in perforating the cloth used for the cover of the book, and fixing to the millboard of the book cover one or more layers of coloured or gilt paper, the coloured surface of the millboard appearing through the perforations in the cloth. *Patent completed.*

1501. J. Broadley. *Improvements in means or apparatus employed in weaving.* Dated May 17, 1862.

This relates—1, To a combination of means in connection with the jacquard apparatus for governing the times and order of motion of shifting shuttle-boxes of looms. 2, To the means of arranging and operating parts for producing gauze weaving, and changes from guaze to other weaving. *Patent completed.*

1502. J. C. Hill and D. Caddick. *Improvements in puddling furnaces.* Dated May 17, 1862.

Here the iron bottom or bed of the hearth, and the arched roof over it, are supported on iron columns; this is done in the following way:—The bed or bottom is supported on short columns, arranged around the outer edge of the bed; on the top of these columns a metal frame rests; this frame is open in the centre, and the outer edge of the frame is of the same shape as the outer edge of the bottom of the hearth. Across the opening in the centre of the frame bars or beams are placed, which support the metal plates forming the bottom or bed. The sides of the hearth are formed with broad flanges, upon which the arched roof is supported; these flanges also rest on iron columns, placed at intervals along the side of the hearth, these columns being made longer than the columns which support the bottom or bed. In order to be enabled to cool the bottom and sides, and ends of the hearth, arrangements are made for directing jets of water against them, and through the ends and under the bottoms of the furnace, and of the hearth, that is to say, at the bottom and bridge, and sides and ends, holes are formed, in order that the jets of water may come in contact with the lining which is placed over those parts of the hearth. *Patent abandoned.*

1503. J. Needham. *Improvements in sheathing or coating iron ships.* Dated May 17, 1862.

Here the inventor sheaths iron ships with copper, Muntz metal, &c., and causes it to adhere thereto by soldering it over its entire surface. He unites the metal sheathing to the iron by material, a non-conductor of electricity. For this purpose he uses gutta percha, or an analogous material, as a cement, which he interposes in sufficient thickness for the purpose. *Patent abandoned.*

1504. C. H. Tessier. *A new safety lock.* (A communication.) Dated May 17, 1862.

The fundamental principle of this invention consists in the application of two series of small blades, the one being situated within the lock, and the corresponding series on the key. In the one series, as in the other, each blade differs from the adjoining one, either in dimensions or in profile. Each individual blade is of extreme mobility, or else maintained by a spring, in some position differing from the normal one, until the two series are brought in juxtaposition by the application of the key to the lock, when, owing to their peculiar form, they assume the position which alone permits of the key turning round. Owing to the extreme mobility of the blades, any pressure that is exerted upon one or more blades of the same series, for the purpose of taking an impression in wax, will cause the blade or blades to recede to a certain extent, and no attempt at taking impressions, however often repeated, whether upon the blades of the lock or upon those of the key, will give a clue to the normal position, which is only produced by the two series meeting each other, and of which there is no trace left when they are disconnected. *Patent abandoned.*

1506. F. E. Sickels. *An improved apparatus for steering vessels.* Dated May 17, 1862.

This refers to a previous patent, dated 21st October, 1862 (No. 2410). The patentee claims governing the action of engines employed to operate the rudders of ships by a tension cord, or an equivalent connection, capable of indefinite extension, for the purposes set forth. *Patent completed.*

1507. J. C. Gore. *Improvements in belt shippers.* Dated May 17, 1862.

This consists of an oscillating double elbow or rivetted T piece, in combination with a single spring locking pawl. A two-notched slide carries the belt-guide, and is provided with a lever or its equivalent, whereby, when the slide has been locked by the pawl with the guide in either of its two portions for guarding the belt, the pressure applied to the lever, or its equivalent, to shift the slide for shipping or shifting the position of the belt from its fast to its loose pulley, or *vice versa*, will first cause the unlocking of the slide, and then give the latter the proper end-way movement. When the movement of the slide has been given, it will be again locked, and remain so locked until the pressure on the lever is reversed. *Patent completed.*

1508. J. Wright. *An improved method of sheathing iron or metal ships, in order to protect them from the action of salt water, fouling, and other such like influences.* Dated May 19, 1862.

Here the patentee proposes to introduce a sheathing of wood planks between the two metals, and the way in which he combines these forms the chief feature of this invention; that is to say—he proposes to isolate the metal skin of the ship from the copper, or other sheathing, by a layer of planks, or a layer of planks supplemented by a layer of india rubber, or felt, or other such gummy substance, and the gist of the invention consists in the particular mode by which he attaches and binds the said substances to the iron skin, and to one another. This he effects by passing screw bolts through the wood and water-tight sheathing into the similar lapped bolt hole on the iron skin, and after screwing it home, holding it tight up by a nut and washer inside. *Patent completed.*

1509. J. Eastwood. *Improvements in machinery or apparatus for removing or wringing hanks of thread or yarns, and all kinds of fabrics, when saturated with liquid.* Dated May 19, 1862.

This consists of a suitable frame of any required form and construction, adapted to the vessel with which the machine is intended to be used, and fitted with a lifting and wringing single or multiple snatch-hook, pressing rollers running, and lifting, and turning gearing. When required, the machinery of the apparatus may be made of a portable form, and mounted upon wheels or otherwise, so as to be capable of being used with different vessels. *Patent completed.*

1510. R. Ramsden. *Improvements in machinery or apparatus for mashing malt.* Dated May 19, 1862.

This consists of an arrangement of machinery and parts whereby a light washing spindle, driven at a high velocity, and having short prongs on it, shall travel about a mash tub so as to effectually wash or mix all portions of the goods and water submitted to the operation. *Patent abandoned.*

1511. G. Macdonald. *Ginning cotton, and for cleaning and preparing any fibrous substance, and also for cleaning or polishing any metal or other substance, designated "Macdonald's fibre buffs."* Dated May 19, 1862.

This consists in the manufacture of rollers or horizontal frames, or any desired shape, of compressed fibrous or other substances. The said fibre or hair is compressed by any mode of pressure screw, or otherwise, and while under the pressure and still in the press, is cut to the required shape, and secured in this shape by any strong adhesive substance, with or without heat; it is let into compartments made for its reception on the surface of the collar, and other shaped buffs, and secured in these compartments with such said adhesive substance and in like manner, each compressed section of the fibre or hair is let in side by side, so as to form a continuous compact surface. *Patent abandoned.*

1512. F. C. Kirkman and R. Swift. *A new and improved joint for uniting or fixing posts and rails of bedsteads, and other articles of furniture, posts and rails in fencing, in the construction of framework for conservatories, emigrants' and other portable houses.* Dated May 19, 1862.

The inventors attach to the corner pillar or post, where the side or end rails are fixed, a wrought or cast hollow metal block, in which are formed mortices or sockets proceeding from the sides of the block at right angles one with the other, as the case may be, and downward from the top of a precisely similar form to that of the tennon to be inserted. The side and end rails at their extremities are set or formed so that they will lap one over the other, and are also provided with a hole punched or drilled in the top portion of the rail to pass over a *I* shaped bolt or pin, which is securely fixed in the hollow metal block by the *I* or head, the bolt end standing upward for the purpose of receiving the side and end bars or rails, which are dropped vertically over the bolt and into the mortice, or notches in their position, as described. The upper portion of the post or cap is provided with a screwed nut fixed on its base, which, upon the sides and end rails being placed in their respective positions, is immediately screwed on to the bolt or pin, and tightly in contact with the side and rails and hollow metal block, forming a complete union of the various parts. *Patent abandoned.*

1513. W. Pickstone and T. Melloden. *An improved fabric in the nature of a cord or corduroy.* Dated May 19, 1862.

Here the inventor makes an improved fabric of this description, by using as the pile weft a silken yarn, produced from what is known as silk waste. *Patent abandoned.*

1514. J. Lee. *Improvements in the construction of traction engines.* Dated May 19, 1862.

This relates, 1, To the wheels of traction engines, and consists in adapting transverse bars of metal to the felloes of the wheels, to ensure greater hold of the said wheels in the ground than heretofore, so as to prevent the slipping round of said wheels, and further in connecting together at will two of such said wheels by plates, extending from the felloes of one wheel to the felloes of the other and opposite wheel, so as to enable the said wheels to be worked in a similar way to a roller. 2, It relates to the balancing of the boiler, which the inventor proposes to balance across the axle, and to elevate and lower the same as desired, by a lever, worked by hand, or by a screw from the fire-box end of the engine. 3, To the supporting of the intermediate wheel which connects the spur wheel with the pinion on the fly wheel shaft, he proposes to employ links for that purpose attached to the axle tree and fly wheel shaft. *Patent abandoned.*

1515. T. Morris, R. Weare, and E. H. C. Monckton. *Improvements in the means and apparatus for the protection of life and property by the agency of electricity.* Dated May 19, 1862.

The patentee claims the application of induction coils and constant batteries to the better protection of life and property, by detecting and securing the persons or the intending burglars or thieves, as specified. *Patent completed.*

1516. T. Morris, R. Weare, and E. H. C. Monckton. *Improvements in obtaining and applying light and heat by electricity.* Dated May 19, 1862.

This consists in obtaining light by passing electricity through vacuum tubes, or other suitable vessels, the electricity used being obtained from frictionall, electro-magnetic, magneto-electro, or hydro-electric machines, and also from other sources. *Patent completed.*

1517. A. V. Newton. *Improved machinery for splitting leather.* (A communication.) Dated May 19, 1862.

This consists in combining with a gauge roll used for regulating the thickness of the leather to be split, a feed roll susceptable of being depressed in a line parallel with the axis of the guage roll, either by the action of the operator or the inequalities of the leather as they pass between the feed and guage rolls, so as to prevent the choking or clogging of the machine, a thing of frequent occurrence in leather splitting machines. *Patent completed.*

1518. M. A. F. Mennons. *Improvements in certain descriptions of breech loading fire-arms.* (A communication.) Dated May 20, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1519. M. A. F. Mennons. *Improvements in the method of, and apparatus for, applying screw power to the locomotion of railway trains on steep inclines.* (A communication.) Dated May 20, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1520. M. A. F. Mennons. *Improved process for the conversion of amylaceous matters into saccharine and other useful products.* (A communication.) Dated May 20, 1862.

This relates to an improved mode of treating amylaceous matters in the manufacturing process of saccharification by acids, with a view to obtain, 1, more perfect extraction of

the saccharine constituents of the raw material than by the ordinary means. 2, Preservation of the nutritive principle of the residues of the manufacture, which are thus rendered advantageously applicable to the nourishment of live stock. *Patent abandoned.*

1521. W. NAYLOR. *Improvements in forging metals, and in power hammers employed therein.* Dated May 20, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1522. R. TALLERMAN and L. A. TALLERMAN. *International ladies' companions.* Dated May 20, 1862.

This consists in the use of a cover for the boot or shoe, made of leather, cloth, or other material. It is placed over the boot, and, when on it, reaches 8 or 9 in. up the leg; it is fastened at the sides by hooks, eyelets, springs, buttons, or other contrivance, under the waist by a strap or elastic band, and at the toes by small pieces of sole leather or other material. *Patent abandoned.*

1523. J. TAYLOR. *Improvements in abstracting heat from liquids and aeriform fluids, and for other purposes.* Dated May 20, 1862.

This consists of an apparatus used, of several parts, amongst others an air-pump or air-pumps, and in the use of mixed liquids of low boiling points in vacuo, or under pressure, acids and chemical compounds in combination with the combined apparatus above named for abstracting heat from liquids, the apparatus being worked by hand or steam power. *Patent completed.*

1524. W. CLARK. *Improvements in paddle and other hydraulic wheels.* (A communication.) Dated May 20, 1862.

This relates to improvements in paddle and other water-wheels, whereby the surface of the float boards or pallets are always kept perpendicular, that is, at right angles to the action of the water. To obtain this result the inventor uses either flat or undulating pallets, each furnished with axes turning in bearings in the sides of the wheels; they are further provided on one edge with a counter-balance weight, which constantly tends to keep their centre of gravity below the centre of oscillation, so as to always maintain the pallets in a vertical position. *Patent abandoned.*

1525. E. FEWKELL. *Improvements in the manufacture of metal tubes and in machinery to be employed for the purpose.* Dated May 20, 1862.

This consists in an improved arrangement and form of rollers, by which the patentee is enabled to make metal tubes of various descriptions taper, parallel-sided, or six-sided in section. He employs three rolls, suitably mounted in bolsters; the axles of these rolls are in the angles of a triangle, the rolls being of a convex form from end to end, in a line with the axles, so that the bite shall come upon the tube after it has entered between the rolls. The bolsters are open in the centre, so that the tube entering through one bolster passes through the rolls, which all revolve in one direction, and out through the opposite bolster. The rolls are geared in any suitable way, and are fitted with proper raising gear, so that they are capable of being adjusted. *Patent completed.*

1526. M. VOGL. *An improved apparatus for protecting houses and other buildings from burglars.* Dated May 20, 1862.

This apparatus is constructed somewhat in the form of a gun-lock, the mainspring and tumbler being enclosed in a metallic case, secured by rivets and by the pivot screw on which the hammer works. One end of the case is furnished with a projecting screw, or other convenient fastening, for fixing the apparatus into the jamb of a door, or the sash of a window, or shutter, or into any other part of a building necessary to be protected from burglars; the lower half of the trigger works one way on a hinge or joint, so as to enable a door or other moveable or closing part of a building to be brought, when closed or shut from the back, to the front of the trigger, the lower part of which then falls, or is brought back by a spring into a line with the upper part, and offers an impediment to the opening of the door or window, or to the motion of any other part of the building attempted to be acted on by the thief. The trigger, when actuated, releases the hammer, which falls upon a nipple on the top of the case, and discharges a percussion-cap, so as to cause an alarum to the inmates, the police, or neighbours. *Patent abandoned.*

1527. J. KENNEDY. *Improvements in ship propellers.* Dated May 20, 1862.

This invention consists in forming propellers by fitting to an axis two blades in the form of the tail of a fish, and in making the blades more or less deep and long, and in altering their pitch according to the speed at which the ship to which the propeller is to be fitted is to be driven. *Patent completed.*

1528. W. PETRIE. *Improvements in vessels for boiling chemical products, as sulphuric acid, and in apparatus for indicating the degree of concentration and temperature of such products in the boiler, which apparatus is applicable to other pyrometric purposes.* Dated May 20, 1862.

The patentee claims, 1, The means of outflow for the boiling liquor, namely, an open shaped vessel fixed within the boiler, and having its run at a level suitable to receive the foam as it rises from the liquor, so that the foam shall settle therein and pour out in a liquid state by a syphon, or through a tube attached to the vessel, so as to trap the vapour within the boiler while the liquid flows out through the tube, as described. 2, The general construction of the vessel for boiling chemical products, arising from the peculiar combination of parts, themselves formed and combined, as describad. 3, Deadening, frosting, or roughing the heated surface of such vessels externally, as described. 4, The particular construction of the pyrometric apparatus, all as described and represented in the drawings. *Patent completed.*

1529. H. B. BARLOW. *Improvements in presses for cotton and other substances.* (A communication.) Dated May 21, 1862.

Here the followers of the presser are connented to elbow levers or knee-joints, which are actuated by right and left handed screws cut in a shaft to which a wheel is keyed; a worm or pinions gears into this wheel, which, in revolving, causes the followers to approach each other, to compress the cotton or other substances. As soon as the bale is corded or lashed, the wheel is turned round in the contrary direction to separate the followers, thereby liberating the bale, which is then removed, and a fresh supply of cotton or other substance to be compressed, is placed in the box or trunk in which the followers work. *Patent completed.*

1530. J. HOPKINSON. *Improvements in pianofortes, and in the hammer-rails of pianofortes.* Dated May 21, 1862.

This consists in a method of applying stoppers of vulcanized india-rubber, cork, or other elastic substance, aided by springs, or other contrivances, and made to press upon certain parts or equal divisions of the strings of pianofortes, so as to divide the vibration, and to produce sounds called harmonics, which differ from the original notes or sounds of the strings. Also in a new hammer-rail, for vertical or upright pianofortes, by which the butt lunges, are brought nearer to the strings, and a quicker and more certain return of the hammers, after having struck the strings, is obtained, and which remedies a defect in the mechanism of these pianos, and compensates for the difference between them and the grand or horizontal pianofortes. *Patent abandoned.*

1531. J. KENNEDY. *Improvements in plates for plating and for forming the outside skin of ships and vessels, and in protecting the same from fouling and oxidation.* Dated May 21, 1862.

This invention consists in forming iron or steel plates, to be employed for the outside skin or surface of ships and vessels, with a rib or ribs rising from that which is to constitute the outside surface of the plate, in forming a rabbet or V groove in the sides of the ribs, in inserting strips of iron or steel into the grooves between every two ribs, space being left between the surface of the plates and the said strips, and in filling up the spaces between the ribs and above the level thereof with white lead. The inventor finishes off the white lead face-smooth, allows it to set and harden, and then paints it, or not, or applies an oily or greasy material or composition thereon, or not, as desired. The object of the metal strips is to assist in holding on the white lead. Care must be taken to ensure the metal being clean and free from oxidation before applying the white lead. *Patent abandoned.*

1533. M. A. LE BRUN VIRLOY. *Improvements in drying and carbonizing wood, peat, and other fuel.* Dated May 21, 1862.

The apparatuses for carrying this invention into effect may be of any convenient form or dimensions, and may be placed either horizontally, vertically, or inclined, and consist of chambers or furnaces made in masonry, iron, or other metal, or even clay or sand, supported and held together by metal plates. In the apparatuses the temperature is maintained higher at one end than at the other; the operation is continuous, and the materials are caused to advance successively from that point where the temperature is lowest to where it is highest. The main features of the invention consist, 1, Introducing wood, peat, and other material at one side or end of a furnace, and withdrawing it from the other side or end in a state suitable for its being employed as fuel. 2, In hermetically closing the doors or other openings to the furnace during the operations, whereby liability to taking fire is avoided. 3, In regulating by means of taps, valves, and registers, the size of the holes in the covers, and in the apparatuses themselves, according to circumstances, to increase or diminish, for example, the activity of the fuel, and the operation, or for regulating the admission and exit of air, gas, and other volatile products. 4, In collecting and removing therefrom a portion of the volatile products after the whole or part of their caloric has been utilized. 5, In utilizing, as far as may be, the same materials and debris of slight value, as well as the combustible gases produced by the operation itself; in short, making use of the waste heat which, in the ordinary processes of drying and carbonizing, is carried away by the vapours and gas escaping at a high temperature. 6, Submitting the wood, peat, or other material to heated first to a low temperature, and gradually increasing it to a high temperature. The operation may, if desired, be facilitated by fans, currents of air, gas, or otherwise. *Patent completed.*

1534. W. BUSH. *Improvements in the construction of ships, and in shields or armour for ships and batteries.* Dated May 21, 1862.

This invention consists in constructing ships intended chiefly as ships of war and floating batteries, as hereafter explained. The patentee forms the ribs and girders of angle irons bolted together, and with timber between every two irons, each rib being composed of two angle irons with timber between them; instead of angle iron bar iron may be used. The outside or hull of the ship may be of timber or of iron, or partly of timber and partly of iron, rivetted or otherwise secured to the ribs. Between the outside or hull and the skin or inner lining of the ship, which he prefers to be of iron, there is a space into which and between the ribs he inserts movable iron or steel armour blocks or plates, which may be made to slide up and down in the said space, to enable the blocks to be inserted and removed as required. Under the port holes on each side of the ship, the blocks are connected to an oscillating platform which carries the gun and carriage. By the employment of an oscillating platform, one half of the usual compliment of guns and men may be dispensed with. The gun after discharge recoils, causes the platform to tilt, and thus brings up the block to close and shield the port hole. He fits a turn-table to the gun carriage to run on, so that if required the gun may be turned and run out to be fired on the opposite side of the ship; or it may be again run out on the same side, its forward motion causing the shield to lower and open the port hole. A space between the armour block and the outside of the ship may be filled with felt, kamptulicon, or other suitable material. The cupola is pierced with holes for rifles. The invention also consists in constructing armour or shields for ships and batteries, however the ships or batteries may be otherwise built, by connecting armour plates and blocks to an oscillating platform, which may be made to work armour or shields at both ends, so that, while the port holes on one side are shielded, the shields are removed from the port holes on the opposite side. The invention further consists in constructing ships with hollow metal keels or keelsons, and with water-tight compartments, for the purpose of containing fresh water and other provisions, as well as affording stability to the ship and for "heeling" her over. *Patent completed.*

1535. A. GILES. *Improvements in constructing floating breakwaters.* Dated May 21, 1862.

Here a series of buoys are used, which are connected together by metal chains, so that the area over which a breakwater extends is divided horizontally into numerous sections, by preference of a lozenge shape, there being a buoy at each angle of a section, and, in some cases, the chain which connects two buoys is further supported by an intermediate buoy. From the chains which connect the several buoys and divide the whole area into sections, there are suspended fringes or net work of chains, in order to break the waves by causing the same to pass through the meshes or openings of the suspended fringes or net work. The outermost and innermost rows of buoys are secured in their places by anchors. By these means the area occupied by a breakwater is divided horizontally by net work composed of chains, the angles of which network are supported by buoys, and from this horizontal net work other net work or fringes are suspended vertically. *Patent completed.*

1536. L. LEINS. *Improvements in travelling bags and apparatus used therewith.* Dated May 21, 1862.

We cannot here give space to the details of this invention. *Patent abandoned.*

1537. H. C. MEYER. *Improvements in the means of stopping or retarding railway and other carriages.* Dated May 21, 1862.

Here the inventor uses the weight of the carriages, or their motive power, as the brake power, to which end he shifts or turns the axles or bearings, and uses eccentric axles or bearings, or raises or lowers the bearings by any other motion, or reverses the eccentric axles or eccentric bearings generally, thus forcing the wheels towards a brake fixed on the body of the carriage. *Patent abandoned.*

1538. W. E. NEWTON. *Improvements in the manufacture of metallic or mineralized fabrics or surfaces.* (A communication.) Dated May 21, 1862.

This consists in coating the surface of a textile, woven, or other fabric with a thin sheet of metal, whereby the substance will be rendered waterproof, and may be applied for a variety of useful purposes in the arts. *Patent abandoned.*

1539. J. OXLEY. *Improvements in making wheels.* Dated May 22, 1862.

This invention relates to improvements in the preparation, by mechanical means, of the parts of wheels, by which is ensured perfect accuracy of fitting, when such parts are assembled; as also for the more perfect maintenance of the parts of wheels in their proper form, when completed, by the prevention of injury to the spoke, tenons, and other joints. Also to the machinery for the production and multiplication of certain parts of wheels, and for their reproduction according to pre-arranged scales of proportions and dimensions. The improvements in the treatment of the felloe pieces of wheels consist in the accurate thicknessing to a guage of each piece, by operating on the two sides at the same time, and this is effected by passing the piece of material to be operated upon between two revolving discs having cutters mounted therein. The machine for thicknessing or planing felloes consists of a bed or gantry, having two moveable head-stocks thereon, and a transverse table, upon which is mounted the carriage and means of holding the piece of material to be operated upon. Each head-stock carries a revolving spindle or shaft, with an overhanging disc, containing one or more adjustable face-cutters or chisels, between which the material is made to pass, and by which it is to cut. The distance between the cutters is capable of adjustment by reason of the movement of the head-stocks, according to the thickness to which the material has to be gauged. Each part of the machine is capable of accurate adjustment and regulation. For the purpose of ensuring accuracy in the after processes of preparing the felloes and other pieces of the wheel, each felloe piece having been examined by the workman, has two gauge points or centre marks impressed upon one face, so that between those gauge points certain gauge holes are bored or drilled in a machine designed for that purpose; a central hole is drilled, of a depth of, say, 1½ to 2 in., and on each side of such hole another gauge hole of lesser depth (say ½ in. to ¾ in. deep) is made. By these holes the materials are accurately applied and adjusted in the various machines in which the subsequent operations are performed, by which means accuracy of reproduction is secured. For the purpose of boring and morticing with greater accuracy and rapidity the naves of wheels for receiving the tenons of the spokes at any required angle with the central axis of the nave, and ensuring that any number of naves for a given size of wheel may at any future time be produced as identical counterparts of naves previously made, the two operations of boring and morticing are performed without the necessity for removing the nave from the axis, shaft, or spindle by which it is caused during the operation, and without removing it from the composed machine. The carriage upon which the nave is mounted for the purpose of being operated upon is capable of being adjusted in relation to the vertical sliding or revolving tool, and the exact angle desired may be obtained and recorded on a scale by means of a pointer arm. For the purpose of forming a more perfect wheel, the patentee cuts an annular groove or recess within the nave for the purpose of inserting a ring or collar of leather, or other material, upon which the inner ends of the spokes will take their bearing, and thus forms an elastic bed or cushion between the end of the spokes and the iron axle-box, and by which means a nearly noiseless wheel will be produced. *Patent com-pleted.*

1540. C. W. SIEMENS. *Improvements in electric tele-*

graph apparatus. (Partly a communication.) Dated May 22, 1862.

This invention consists in communicating codes of signals by particular mechanical agency, by which great rapidity and accuracy of transmission is obtained. In the specification to former letters patent granted to the present patentee, and bearing date the 25th of February, 1859 (No. 512), he described an arrangement where types were employed, having elevations or depressions representing the letters or signs to be transmitted, which typers were arranged in a row, or in rows, and acted consecutively upon a contact lever in connection with a galvanic battery, or other source of constant currents of electricity, so as to cause it to make and break contact with the recording instrument, thereby producing signs exactly corresponding with the form of the types. In the present invention the arbitrary succession of signals, constituting a letter, number, or sign, is represented by a type or by types, which is or are so formed that, on being passed along against a contact lever, a series of currents is passed through the line wire, which currents are produced by a magneto-electric machine or other apparatus that produces a regular succession of currents, the same being moved in such a manner by the same mechanism, which imparts motion to the types, that, at the moment when the type completes the line wire circuit, a positive or negative current, such as may be required, is produced and transmitted through the line wire. *Patent abandoned.*

1541. J. H. Perry. *Curing diseases of the human body by magnetism.* Dated May 22, 1862.

This invention consists of an apparatus which the patentee denominates the magnetic equilibust, or regulator of the human health. The apparatus is formed of suitable design and dimensions, with moveable and adjusting parts, capable of receiving and supporting the human body in a sitting or reclining position, and the part which receives and supports the head is fitted with a magnetic cap or other vestment, in which polarized magnets are arranged, as hereinafter described. The arm rests are fitted with one or two galvanic batteries, and the part which supports the back of the patient a belt, in which a number of polarized magnets are also arranged, is fitted. This belt is intended to pass round the body or loins, and is provided at the ends with suitable fastenings for securing it in the required position. At the seat of the frame a cushion, in which a galvanic battery is fitted, is also placed, and upon the part which supports the feet another galvanic battery is mounted. The batteries for the feet and seat are square, and those for the hand are semi-cylindrical, and are formed with, or adapted to, square, cylindrical, or semi-cylindrical metallic chambers, furnished with heaters, to be used as circumstances may require. The square battery for the feet is fixed to a semi-cylindrical metallic chamber, and mounted upon an axle, so as to be capable of being moved by the foot. The parts of the semi-cylindrical batteries upon which the hands rest are also mounted upon pivots, or universal joints, so as afford free movement to the hands. The seat battery is also mounted upon an axle or dead pin to allow the necessary movement thereof. By means of the magnetic vestments and galvanic batteries a permanent, though insensible magnetic current, is established throughout the body, from the head to the feet, without having recourse to any additional conductor than the polarized magnets, the galvanic batteries, and the vital principal of animal life. Small batteries to be used without heat are also placed in the soles of the shoes or boots. *Patent completed.*

1542. E. De La Bastida. *A new process for the production of designs in relievo, and in deepening on sheets of india-rubber of any length whatever.* (A communication.) Dated May 22, 1862.

This invention consists in the production of cheap ornamental designs. The patentee takes a number of small separate pieces of metal, or other suitable material, having upon them deiigns sunk or in relief of an ornamental character, and with them, upon an iron table, composes numerous parts of types, and thus produces the patterns for carpet or other article to be made. He then places a sheet of india-rubber, or india-rubber compound, prepared for vulcanization, and of suitable thickness, upon the pattern composed of ornamental designs, and brings down a plate of metal with sufficient force to press the sheet of india-rubber into or upon the design, and he takes an exact impression thereof. He then heats the table and vulcanizes the india-rubber, after which it is unchanged by moisture or atmospheric influences. *Patent completed.*

1543. G. Crawford. *Improvements in musical instruments.* Dated May 22, 1862.

This invention relates to a peculiar construction of musical instruments capable of being played upon by means of keys similar to a pianoforte, and consists in substituting for the strings hitherto used in pianofortes, a number of metal prongs or "vibrators," somewhat similar to those used in musical boxes, or similar to the musical pitch forks properly tuned and acted upon, either by "jacks," as in the harpsichord, or by hammers brought into play by a percussion action on the keys. Another part of this invention relates to an improved action, which is applicable to pianofortes, as well as to the improved instrument, whereby greater nicety of touch, with increased power of blow and effective check action, at a reduced expense, is obtained. These improvements consist in making the butts of the hammers bevelled or curved inwardly on their under surfaces, and in causing the fly to act directly upon such butt, thereby dispensing with the use of stickers and levers. The bevel or curve forms also an efficient check to the fly, preventing it from being thrown too far forward. One portion of these bevels may be made adjustable, so as to regulate the check action. It is proposed to apply springs under the butts for the purpose of assisting in throwing the hammer from off the prong or string after striking, and so affording a more effectual repeat action, and giving greater elasticity of touch. *Patent completed.*

1544. J. Needham. *Improvements in breech loading fire-arms, and cartridges for such fire-arms.* Dated May 22, 1862.

These improvements in breech loading guns consist in mounting and fitting the barrel of the gun in such manner that, by the motion of a lever, it is first moved longitudinally away from the breech piece, and then swivels or moves on a centre out of the line of the gun and so exposes the breech end of the barrel or barrels. The patentee further makes the breech piece with a parallel recess for each barrel to receive the rear end of the cartridge, say, to the extent of ⅜ths of an inch. The object of the barrel first moving forwards is to withdraw this length of the exploded cartridge out of the recess before mentioned, so that when the barrel is swivelled or moved out of the line of the gun, the projecting end of the cartridge case which was in the breech recess will present a good hold whereby to withdraw it from the barrel. Another cartridge may be then inserted in the barrel, which is replaced in position for firing by the reverse motion of the lever before mentioned. The second part of the invention relates to improvements in a breech-loading gun of the invention for which a patent was granted to the present patentee (No. 184), dated October 2, 1852, and consists of a hooked picker or instrument placed below the hinged breech piece; it lies along underneath this, and is jointed to the stationary screwed part. When the rotary screwed part that closes the breech is screwed back, the hooked end of the picker projects slightly beyond the nose of the breech-piece, and which in raising the breech piece out of the line of the barrel, takes hold of the end of the cartridge case, and pulls it out of the barrel. The third part of the invention relates to shot cartridges, and consists in making them of thick and stiff substances to the extent occupied by the powder, and the wad separating it from the shot, but beyond that point of a slight substance, and closing the end thereof by gathering it together like the mouth of a tied sack; but instead of tying it round, he drops a slight metal ring on it, and turns the edge back on the ring, which readily and effectually encloses the shot, and forms less obstruction thereto in shooting than the ordinary method of securing. Another part of the invention relates to guns in which the breech piece receiving the charge is pivotted near the rear or butt end, and is moved backwards and forwards in order to move in and out of the line of the barrel for loading and firing. According to these improvements, he fixes the female screw to the breech end barrel, which receives a screwed metal socket, within which the back end of the breech chamber is pivotted. The charge chamber of this breech piece terminates of a conical form, and is reduced to a small hole at the rear end, where it emerges, and by which the needle enters to explode the charge; or this aperture may serve for the entrance of the fire of the cap, the nipple for which may be placed centrally at the extreme end of the breech piece. *Patent completed.*

1545. S. and F. Turnbull. *Improvements in the manufacture of floor cloths.* Dated May 22, 1862.

The patentees claim, 1, The application of a surface of paper to the canvas, or foundation of woven fabric, of floorcloth, or other like coverings, as and for the purposes described. 2, The manufacture of floor and other coverings of painted paper, in the manner described. *Patent completed.*

1546. J. Kennedy. *Improvements in protecting the sides and decks of ships from the effects of projectiles.* Dated May 22, 1862.

This invention consists in protecting the sides of ships by means of wire ropes, in coils or otherwise, supported by metal springs. Instead of, or in addition to, the wire ropes, plates may be used. For the decks the inventor uses metal plates, backed or supported on metal springs. The object of the invention is to afford at the same time a resisting and yielding armour. *Patent abandoned.*

1547.

The nature of this invention consists in the application of rollers, composed wholly or in part of India-rubber, or other material of which india-rubber is a principal component, to the purpose of wringing clothes, or pressing water from fabrics, and also in a novel and simple construction and arrangement of the different parts of a wringing machine to accomplish the desired object in a convenient and perfect manner. While the form of construction renders wooden rollers practicable, those made of india-rubber, or other similar material, present several and decided advantages. The frame, which is entirely of metal, is constituted in part of levers, which perform all the offices of screws and springs, without possessing any of their objectionable features. By simply placing this "wringer" upon the side of the vessel in which, or on the side of the machine by means of which, the washing is done, without any adjustment or fastening, it is ready for operation, and remains firmly in its position. It may also be removed with the greatest facility. *Patent completed.*

1548. P. R. Hodge. *Improved dinner, supper, breakfast, or dessert plate.* Dated May 22, 1862.

This invention consists in the peculiar conformation of the plate, the rim or edge of which is so formed as to have either an annular continuous recess, or groove, around the body of the plate, or one or more recesses sunk or moulded into the rim, for the purpose of placing the various condiments, conserves, &c., in the said groove or recess, keeping them separate from the food on the plate, so that they may be used at discretion. *Patent abandoned.*

1549. G. Barlow. *Laying submarine telegraph cables.* (A communication.) Dated May 22, 1862.

This invention consists in laying submarine telegraphic cables by partially supporting them below the surface of the water during the paying out of the same by means of friction clutches, or appliances, supported from the ship's sides. *Patent abandoned.*

1550. H. Cook. *Improvements in electric batteries.* (A communication.) Dated May 22, 1862.

This invention has for its object the construction of a battery which shall work during several months without it being necessary to interfere with it, or renew any of the chemical agents which are employed to develope currents of electricity. The invention relates to a modification of that description of battery known as the Daniell's battery, and consists in the employment of sand, or any other pulverulent substances unattackable by acids, in place of the porous vessel ordinarily used. In combination with this sand, or other substance, sulphate of copper, in the state of powder, is employed in sufficient quantity to last several months. *Patent completed.*

1551. W. Roberts and T. Greenacre. *Improvements in cocks or valves for steam or other fluids.* Dated May 22, 1862.

In constructing cocks or valves according to this invention, the stem or spindle of the valve is caused to pass through a stuffing box at the top of the barrel or body within which the valve works. The stuffing box is divided from the barrel or body by a petition through which the stem or spindle of the valve passes, and there is a collar on the stem or spindle which is enclosed between the upper side of the partition and the bottom of the stuffing box, which is screwed down into its place over the collar, the interior of the stuffing box having a screw thread cut in it to admit of this being done. The upper or outer end of the stem or spindle of the valve has a handle fixed upon it, by means of which it may be turned round, and the inner or lower end of the stem or spindle has a screw thread formed upon it, which fits into a female screw formed in the upper end of the piece forming the valve; and the valve, which it is preferred should be conical at the bearing surface, and have a conical seat, can be raised off its seat by turning the stem or spindle, and causing the screw thereon to descend through the female screw. The valve, when it is raised, is received into the upper part of the barrel or body, where there are projections or ribs which guide the piece forming the valve, and prevent it turning whilst it is being raised or lowered. The seat of the valve is made separate from the barrel or body, and is screwed into its place at the lower end thereof from the outside. The outlet for the fluid to pass away from the cock or valve is on one side of the barrel or body. *Patent completed.*

1552. J. W. Evans. *Improvements in obtaining motive power by machinery.* Dated May 22, 1862.

To a horizontal bar the inventor connects at each end a rod, each of which rods is connected to a crank on a toothed spindle, upon the axis of which fly wheels are fixed. The toothed spindles drive toothed wheels, upon the axis of which spindles carrying tappets are fixed. Then from the horizontal bar he suspends a pendulum or heavy weight, and at each end of the course of the pendulum he places a hammer or spring. The action is as follows:—He causes the horizontal bar to rock and set the pendulum in motion; through the connecting rods the crank spindles and fly wheels are made to revolve, and through the toothed wheels the tappet wheels are also made to rotate, and the motions are so calculated, that upon the pendulum reaching the end of its course, first in one direction and then in the other, the tappets release the hammers or springs, which, falling or pressing on the pendulum, keep up its action. The motive power is taken from the fly wheel shafts or from the rocking bar, or from both. *Patent completed.*

1553. G. F. Goranson. *Improvements in the construction and arrangement of armour plates.* Dated May 22, 1862.

According to this invention, it is proposed to employ a number of ribs or rails having enlarged or expanded heads, of a round or other transverse section, which are secured by bolts to the surface to be protected. Over these ribs are laid transversely one or a series of plates bent so as to conform exactly with, and fit accurately, the corrugated surface produced by the ribs; by this system the head of each rib or rail serves to hold the plates firmly in their places, and, when a series of plates are thus bent and laid one over the over, the inner plate or plates will always hold the outer ones securely. The surface of the plates so disposed presents a series of corrugations or ribs, and in the hollow between these corrugations may be driven round or other shaped bars, so as to fill or partially fill the intervening channels or grooves. *Patent abandoned.*

1554. P. McGregor. *Improvements in spinning and doubling cotton, &c.* Dated May 23, 1862.

This invention consists in a combination and arrangement of machinery for regulating the amount of twist in the yarn. In performing the invention, the patentee applies a worm or tin drum shaft or other shaft in the carriage for driving the spindles; this worm gears into a wheel, to the shaft of which is fixed a wiper or tappet, acting when the carriage is out upon a lever jointed to the headstock; this lever, by means of a connecting rod shaft, or other equivalent agent, liberates a catch when the twist is completed, and allows the driving strap to be moved in the usual manner, either by a spring or weight, or by the action of a cane shaft. *Patent completed.*

1555. R. Blacklidge. *Improvements in the preparation of materials for sizing, dressing, or finishing warps, yarns, textile fabrics, &c.* Dated May 23, 1862.

This invention consists in treating flour of wheat or other cereal grain, rice, sago, or any other amylaceous substance or substances, with diastase, for the purpose of procuring a gummy matter, with which the inventor incorporates lapis calminaris, terra alba, and alumina, to any required extent, for the purpose of obtaining a compound suitable for sizing or dressing warps, yarns, textile fabrics, or paper, and also for thickening colours. *Patent abandoned.*

1556. C. De Bergue. *Improvements in the manufacture of metal reeds for weaving.* Dated May 23, 1862.

This invention has reference to regulating the speed (at the starting and stopping) of the winding drums, or reels, to the treatment of the wire while passing from one reel to another, including improvements in the tools or apparatus for filing, planing, gouging, polishing, or otherwise treating the wire, and to the construction and working of the bobbins and fliers for carrying the bands or binders to be used in the setting machine, and of the driver, or "beater up," to be used in the said machine, and comprises much detail, which we cannot produce here. *Patent abandoned.*

1557. W. E. Wiley. *Improvements in penholders.* Dated May 23, 1862.

This invention relates to those kinds of penholders called "Orthodactylic penholders," that is, penholders having a series of finger and thumb plates disposed on their surfaces, by which plates the correct position of the fingers and thumb on the said holders is obtained. Each of the said finger and thumb plates is ordinarily made of a separate piece of metal, and is fixed to the penholder by soldering, or by means of a sliding ring. This invention consists, 1, In making a set or series of the said finger or thumb plates of one piece of sheet metal, by which method of manufacture great economy in their production is effected. 2, In fastening the finger and thumb plates of Orthodactylic penholders, when each of the said plates is made of a separate piece of metal, to the penholder, by means of small tongues, or projecting pieces, on the said plates engaging in piercings in the penholder, the said tongues, or projecting pieces, being fixed with or without the addition of solder. *Patent completed.*

1558. J. Webster. *Improvements in coating and indurating metals.* Dated May 23, 1862.

The object of this invention is to coat iron or steel articles, or surfaces of copper, and other metal surfaces, with an alloy, which will harden the surface to which it is applied. In carrying out this invention, the patentee takes the article, if of wrought iron or steel, and thin or light in substance, and brings it to a red heat in a furnace, and he coats the article with an alloy composed of the following metals, mixed in or about the following proportions, viz., three parts of pure tin and one part of antimony. In making this alloy, he first melts the antimony, and then adds the tin thereto while the antimony is in a molten state, and of this alloy, either in a cold or melted state, he takes one part, and mixes therewith two-and-a-half parts of copper. In doing this, he first melts the copper, and then adds the alloy of tin and antimony; or, the copper having been melted, he adds the antimony alone, and stirs it well into the copper. He then adds the tin, and amalgamates the whole. This mixture is to be kept at a low red heat if used for sheets and other thin forms. The surface of the mixed metals, or melted alloy, is covered with a flux, consisting of one part of the the yellow prussicate of potass and two parts of either caustic or carbonate of potass. The molten alloy should be covered to a depth of 2 in., and the bath will then be ready for use. The sheet or article of wrought iron or steel to be operated upon is then to be heated to a red heat, and in this state it is to be passed through the flux into the bath of the molten alloy, by which operation the article will be completely coated, and its surface indurated or hardened. For articles made of cast iron and copper, this mixture of metals, or alloy, will also answer, and may be applied in the same manner. *Patent completed.*

1559. J. Ward and J. Dewick. *Improvements in the manufacture of textile or looped fabrics.* Dated May 23, 1862.

This invention relates to certain new arrangements and combinations of parts, supported by an ordinary framework consisting of end standards, and, where the length of the frame makes it requisite, by intermediate standards also, the said standards being connected together by a top tie bar and one tie bar. In this improved machinery or apparatus there is, according to one modification of the invention, a needle bar, to which a to and fro movement is imparted as follows, that is to say:—There are two or more short links upon one end, to which the needle bar is secured; the other ends of the links are hinged to brackets attached to a spindle bar lying below and at the back of the needle bar. There is also a horizontal bar attached to the needle bar at each end of the machine; the front end of the horizontal bar works on a pin or axle secured fast at the position required in the slot of a link moving on an axle secured to the front framing of the machine. There are two cam shafts, one at the back and the other at the front of the machine. The needle bar is moved by cams on the back shaft, and by intermediate links and levers. Each of the aforesaid cam shafts is provided at one end with a bevil wheel, which wheels gear into similar wheels on each end of a short horizontal shaft at one end of the frame; the bevel wheels on this shaft are twice the size of the bevel wheels on the cam shaft. The cam shafts will make two revolutions while one revolution is being made by the short shaft. This short shaft is also provided with suitably arranged wheels. *Patent completed.*

1560. E. Molino. *Improvements in apparatus used in weaving.* Dated May 23, 1862.

The patentee claims, 1, The employment of an ordinary magnet for moving the shuttle to and fro, instead of an electric magnet. 2, The method of arranging the magnet with or without its mounting of iron bars. 3, The peculiar mode of constructing the shuttle. The invention cannot be fully described without reference to the drawings. *Patent completed.*

1561. E. Maw. *Improvements in constructing ships, vessels, forts, and batteries.* Dated May 23, 1862.

This invention consists in certain improvements in constructing ships, vessels, forts, and batteries. For these purposes the inventor constructs hollow armour plates and backing, by combining corrugated sheet metal with other forms or descriptions of iron, steel, or homogeneous metal, the corrugations of one or more of these corrugated plates abutting against each other, or against a middle uncorrugated plate or plates. By means of a middle plate he facilitates the jointing and overlap of the corrugated plates, and reduces the strain upon the fastenings. In order to produce a uniform bearing and resistance when using middle plates, he forms in such plates, at such intervals as may be desired, corrugations corresponding with the corrugations of the other plates, the other parts of the middle plates being left plain or flat, by which means what may be termed curved tongues are produced, which contribute with the other parts of these plates materially to retain all parts in a sound condition. In order to prevent the splitting of the solid iron armour plates, similar to those now in use, ferrules or casings in one or more parts are used, shrunk into an inner tube made in whole or in part, of iron, steel, or homogeneous metal, and he further covers the bolts or rivets—to be made either hollow or solid for fastening the armour plates or backing together, or to the vessel or backing—with casings of steel, iron, or homogeneous metal, for the purpose of strengthening them, and preventing them splitting. *Patent abandoned.*

1562. A. Samuelson. *Improvements in hydrostatic presses.* Dated May 23, 1862.

This invention relates to a peculiar construction and arrangement of accumulating apparatus to be used in combination with hydrostatic presses for crushing seeds, nuts, or other fatty substances, and consists essentially in the adaptation to such presses of an accumulator, so arranged that one weight produces two distinct pressures, one considerably greater (by preference nine times greater) than the other. This is effected in the following manner:—There is a lower cylinder containing oil, water, or other liquid; in this cylinder a ram is fitted in the usual manner, and above this ram, and forming a continuation of it, is an upper ram about ⅓ the diameter of the lower one. This smaller ram is inserted into an inverted cylinder, also containing oil, water, or other liquid, and which cylinder is imbedded in and forms part of the weight or load. There is no communication between the two cylinders, each being charged by its own pump or pumps through proper pipes; these pipes also communicating with the stop-boxes attached to the presses. A stop-box may be fitted to each press, or one stop-box may communicate with and actuate several presses. Each stop-box is fitted with three ordinary cone valves, namely, one communicating with the low-pressure cylinder of the accumulator, one with the high-pressure, and the third to discharge the presses. The spindles of these valves have rather coarse pitched threads upon them, working through the packing glands as nuts, and above these threads, on the tops of the spindles, are cams actuated so as to open and shut the valves by a central cam and handle, and so arranged that, by one revolution of this central cam, all the valves are successively open and shut as required in the operation of oil pressing. *Patent completed.*

1563. W. Clark. *Improvements in socks and stockings.* (A communication.) Dated May 23, 1862.

This invention consists in making the above articles of supple leather, and to this end the inventor prepares, cuts out, and sews the said leather or skin either by hand or mechanical process, in the required forms or shapes, goffering the skins, if desired, for the purpose of cambering certain parts thereof. *Patent abandoned.*

1564. G. T. Livesey. *Improvements in purifying illuminating gas, &c.* Dated May 26, 1862.

One part of this invention consists in purifying illuminating gas produced by the distillation of coal from the impurities, such as ammonia and sulphuretted hydrogen contained therein, by means of sulphric acid. Another part of the invention consists in converting the products resulting from the before-described method of purifying the gas, as also the ammonical liquor resulting from its previous purification, by condensation into useful or marketable substances. *Patent abandoned.*

1565. J. Harrison and R. Parkinson. *Improvements in rollers for preparing spinning, doubling, sizeing, winding, warping, and weaving.* Dated May 26, 1862.

This invention consists in making the rollers or drums of the various machines employed in preparing, spinning, doubling, sizeing, winding, warping, and weaving, of sheet iron coated with lead, or a combination of lead with other metals or materials, which sheet iron is known to the trade as the "patent coated sheet iron," instead of making such rollers of turned sheet iron or brass, or other metal, or of wood, as now customary, thereby reducing the cost both of material and labour. *Patent completed.*

1566. W. and J. Harrison, J. Oddie, and W. Parkinson. *Improvements in machinery for winding, sizeing, and weaving.* Dated May 26, 1862.

These improvements in winding machines consist of an improved mode of constructing the rails for the bearings of the spindlee. The improvements in machinery for sizeing consist in supporting the end of the cone shaft in a swivel bearing, acted upon by a lever for throwing a pinion on the cone shaft, in or out of gear, with the wheel to be driven. The improvements in machinery for weaving consist, 1, In applying a regulating screw to the bearing of the tappet shaft, for regulating the depth of gear of the wheels. 2, In connecting the picking tappet to the tappet shaft, by means of a bush fixed to the shaft, on which bush, and on the picking tappet, teeth are cast; by this means the picking tappet is securely held, and its position can be easily regulated. 3, In applying a catch to the incline which passes through a slot in the breast beam, and serves as a stop to the lever supporting the weft fork, for applying the break to the fly-wheel when the weft motion acts. *Patent completed.*

1567. C. D. Bergue. *Improvements in iron framing.* Dated May 26, 1862.

This invention embraces the constructing iron frame work of two series of ribs or beams, one series of them shaped and applied to give the desired sections or form in one direction, and others shaped and applied cross ways to the first series to give the required sections or form in a cross direction; and the two series being rivetted or connected together and further strengthened by struts, or lies, or bars, applied in a direction at right angles, or nearly so, to both series of beams, and rivetted or connected to both, and fitted where necessary with filling up or bedding pieces for affording additional support to the intended coverings or surfaces. *Patent abandoned.*

1568. C. Brakell, W. Hoehl, and W. Gunther. *Improvements in steam and other motive engines.* Dated May 26, 1862.

This invention relates, 1, To valve gear for reciprocating engines, and to a mode or arrangement and combination of mechanism for actuating valves for admitting and cutting off the supply of steam, so as to work it at various degrees of expansion. 2, To improvements upon rotary steam-engines or wheels acting by the momentum of the motive power employed. In this class of engines, in order to obtain the greatest efficiency and economy, the turbine wheel should have a velocity bearing a certain proportion to the velocity of the entering steam or other motive power. *Patent abandoned.*

PROVISIONAL PROTECTIONS.

Dated July 28, 1862.

2134. W. Maugham, Prospect-place, Wandsworth-road. Improvements in the manufacture of effervescent beverages.

Dated Oct. 8, 1862.

2720. M. A. F. Mennons, 24, Rue du Mont Thabor, Paris. Improvements in self-inking hand stamps. (A communication.)

Dated Nov. 13, 1862.

3053. A. Twaddell, Glasgow, manufacturer. Improved arrangements for dressing or sizeing warps.

3057. J. Slack, Manchester, water filter manufacturer. Improvements in nursery swings and cots.

3059. W. E. Gedge, 11, Wellington-street, Strand. An improved machine working by compression and expansion of air. (A communication.)

3063. R. A. Brooman, 166, Fleet-street, patent agent. An improved means or apparatus for shunting trains. (A communication.)

3065. C. G. Kopisch, Bishopsgate-street Without, merchant. Improved apparatus for propelling, steering, and ventilating vessels.

Dated Nov. 14, 1862.

3066. E. S. Cathels, Shrewsbury. Improvements in apparatus used in the manufacture of gas.

3067. E. B. Wilson, 5, Parliament-street, Westminster, engineer. Improvements in the method of conveying air, steam, gases, and fluids to oscillating or vibrating cylinders and vessels, and in the apparatus employed therein.

3069. S. Roberts, Sheffield, manufacturer. An improvement in frames for containing stoppered bottles and jars.

3071. V. J. Cassaignes, Gavundun, Canton de Montflanguin, France. Improvements in stereoscopes.

Dated Nov. 15, 1862.

3073. J. S. Clegg and J. Slater, Oldham, machinists. Certain improvements in carding engines.

3075. E. Kirby, Birmingham, merchant's clerk. A new or improved pulley for tightening the cords of window and other blinds.

3079. E. H. Duru, Poictiers, France, sculptor. An improved motive power engine.

3081. W. H. James, Old Kent-road, civil engineer. Improvements in steam engines.

3082. J. Wilson, 2, Royal Exchange-buildings, civil engineer. Improvements in hydraulic pumps. (A communication.

3083. G. Gray, Greenwich. Improvements in the manufacture of wheels.

Dated Nov. 17, 1862.

3085. C. Binks, Parliament-street, Westminster. Improved methods of obtaining oxygen and chlorine gases.

3087. W. Dobson, Nottingham, lace dresser. Improvements in lace dressing frames employed in the dressing of lace or other fabrics.

3089. W. Williamson, 133, High Holborn, mechanical engineer. Improvements in washing, wringing, and mangling machines.

3091. G. Richards, Caroline-street, Bedford-square. Improvements in the construction of ordnance and firearms, and in the projectiles to be used therewith.

Dated Nov. 18, 1862.

3093. J. Arbós, Barcelona, Spain, doctor. Improvements in generating certain gases for lighting and heating, and in apparatus employed therein.

3095. W. H. Burnett, Margaret-street, gentleman. Improvements in the mode of working telegraphic lines, and in instruments and apparatus employed for telegraphic purposes.

3097. C. W. Harrison, Lorimer-road, Walworth, engineer. Improvements in looms for weaving.

3098. C. Nield, Cheadle, Chester, accountant, and J. Hopkinsbn, York-place, Manchester, engineer. Improvements in fire alarums and indicators of temperature.

3099. R. Brown, Birmingham, gentleman. Improvements in warming and ventilating, more especially applicable to buildings, carriages, and ships, and in apparatus to be employed for that purpose.

3101. R. Beck, Peartree-cottage, Upper Holloway. Improvements in reading glasses and magnifiers to be simultaneously used with both eyes.

Dated Nov. 19, 1862.

3103. L. Lenzberg, 492, Oxford-street, manufacturer. Improvements in the apparatus for raising and lowering Venetian and other blinds.

3107. S. S. Brown, Ellesmere Works, Runcorn, Chester, manufacturer. Improvements in the manufacture of elastic fabrics or garments.

3109. R. A. Brooman, 166, Fleet-street, patent agent. Improvements in tubular boilers, condensers, and superheaters. (A communication.)

3111. J. B. Edmonson, Manchester, railway ticket manufacturer, J. Carson, foreman, and J. Blaylock, Carlisle, machinist. Improvements in machinery for printing, numbering, and dating railway and other tickets.

3113. G. A. Bucholz, Montague-place, Clapham-road, engineer. Improved mode of manufacturing semolina and flour, and in apparatus to be employed in such manufacture.

Dated Nov. 20, 1862.

3114. J. T. Hutchings, Inkermann-terrace, Charlton, boot and shoe manufacturer. Improvements in the construction of waterproof boot and shoe soles.

3115. J. Jewsbury, Kinver, Stafford, machinist. An improvement or improvements in machines for raising weights, which improvement or improvements may also be applied to lathes.

3117. G. W. Holdham, Moll Spring, Honley, near Huddersfield, dyer. Improvements in preparing and dyeing

silk waste, flax, hemp, Indian or China grass, or other similar fibrous substances.

3119. R. A. Brooman, 166, Fleet-street, patent agent. A method of, and apparatus for, indicating and recording the course of ships and vessels. (A communication.)

3121. F. Seiler, 2, Thavies-inn, Holborn, gentleman. Improvements in motive power engines, and in apparatus for conveying and distributing motive power.

Dated Nov. 21, 1862.

3125. W. Sinnock, Nicholas-lane, mechanical engineer. Improvements in the treatment and combination of fibrous and and other materials, and in the arrangement of apparatus for manufacturing the same.

3127. J. Townsend, Glasgow, manufacturing chemist. Improvements in damping and preserving vegetable substances, and vegetable and other textile materials and fabrics.

3135. G. G. Sanderson, Parkgate Iron Works, Rotherham. Improvements in armour for fortifications and floating and other batteries.

3137. C. A. Orth, Church-road, De Beauvoir-square, saddler. Improvements in apparatus for obtaining and applying motive power.

3139. A. Sutton, Rue Boursault, Paris, engineer. An improved construction of time indicator for public vehicles and other uses.

Dated Nov. 22, 1862.

3141. W. Nethersole and C. Buckland, Swansea, engineers. Improved safety signals for firearm practice.

3143. C. De Bergue, Strangeway's Works, Manchester, engineer. Improvements in machinery or apparatus for the manufacture of metal reeds for weaving.

3145. W. Clark, 53, Chancery-lane, engineer. Improvements in candle lamps. (A communication.)

3147. J. Webster, Birmingham, engineer. Improvements in the construction of burners and blow-pipes.

Dated Nov. 24, 1862.

3152. J. Barclay, Vulcan Foundry, Kilmarnock, manager. Improvements in the construction and arrangement of rollers to be used in printing textile materials or fabrics, and in apparatus for drying and finishing the said materials or fabrics.

3153. J. H. Johnson, 47, Lincoln's-inn-fields, gentleman. Improvements in burnishing metal surfaces, and in the machinery or apparatus employed therein. (A communication.)

Dated Nov. 25, 1862.

3157. J. Moule, 15, Seabright-place, Hackney-road, manufacturing chemist. An improved method of deodorizing mineral oils and hydro-carbons.

3159. A. L. Woolf, Birmingham, wholesale jeweller. A new or improved metallic alloy.

3160. E. Wadsworth, Macclesfield, silk manufacturer. Improvements in machinery used in the manufacture of certain description of braid.

3163. G. Henderson, 7, Mincing-lane. Improvements in steam-engines. (A communication.)

3165. A. V. Newton, 66, Chancery-lane, mechanical draughtsman. Improvements in sewing machines. (A communication).

3167. T. M. Elton, St. Luke's Soap Works, Golden-lane, Barbican. Improvements in the manufacture of soap, and in the machinery employed therein.

Dated Nov. 26, 1862.

3169. J. Aspell, Middleton, Lancaster, manufacturer, and E. Booth, manager. Certain improvements in looms for weaving.

3171. F. Palling, Esher-street, Upper Kennington-lane. An improved fountain penholder.

3172. J. F. Foveaux, Strand, surgical instrument maker. Improvements in apparatus for pulverizing or dividing liquids into spray. (A communication.)

3173. W. Austin, Furnival's-inn-place, Holborn. An improved material for the manufacture of cartridge cases, applicable also for tubing and various other useful purposes.

3175. A. V. Newton, 66, Chancery-lane, mechanical draughtsman. An improved mode of preparing oxide of zinc as a pigment. (A communication.)

Dated Nov. 28, 1862.

3188. J. T. Caird, Greenock, engineer. Improvements in steam-engines.

3190. F. Boecke, Berlin, engineer. Improvements in sewing or uniting fabrics, and in the machinery or apparatus employed therein.

3196. J. Adams, Bridgehouse, Bow, and W. C. White, King-street, Regent-street. Improvements in apparatus for boiling and evaporating.

Dated Nov. 29, 1862.

3202. T. Lloyd, Liverpool, coach builder. Improvements in, and applicable to, the wheels of vehicles.

3206. J. C. Robertson, Gracechurch-street, and W. C. White, King-street, Regent-street. An improved tap or cock.

3208. D. Sutton, Banbury, farmer. Improvements in apparatus for washing linen and other fabrics and garments.

3210. A. R. K. Penson, Ferryside, Carmarthenshire. Improvements in apparatus used for warming railway carriages. (A communication.)

Dated Dec. 1, 1862.

3212. H. L. Emery, 72, Sloane-street, Chelsea, agricultural implement maker. Improvements in thrashing machines.

3214. G. F. Griffin, New Adelphi Chambers, engineer. Improvements in the permanent way of railways.

3216. J. Irwin, Wellingborough, Northampton. An improved machine for cultivating land.

3224. A. V. Newton, 66, Chancery-lane, mechanical draughtsman. Improvements in the construction of steam and other vessels. (A communication.)

Dated Dec. 2, 1862.

3226. H. Twelvetrees, Bromley, manufacturer. An improved sawing, filing, mortising, and turning apparatus.

3228. P. Brassert, St. Anne's-road, Brixton. Improvements in apparatus for saving life and property in cases of fire or burglary.

3232. T. Cook, Manor-place, Walworth, machinist. Improvements in envelope folding machinery.

3236. A. P. Charles, High-street, Wapping, soap and candle manufacturer. Improvements in candles and night lights, and in the lamps or apparatus for burning the same.

3238. H. J. Simlick, Osborne-place, Whitechapel. Improvements in the manufacture of cigar and pipe lights.

Dated Dec. 3, 1862.

3240. H. Wilde, Manchester, engineer. Improvements in electro-magnetic telegraphs, and in apparatus connected therewith.

3242. R. B. Thomas, Anderton. An improved apparatus for turning over the leaves of music.

3246. I. I. Abadie, Rue de Mulhouse, Paris, commission agent. Improvements in the manufacture of imitation lace and guipure veils and other analogous articles.

Dated Dec. 4, 1862.

3250. J. Grant, Albion-place, Maidstone, farmer. Improvements in the construction of turn-tables for portable railways.

3252. J. Braddock, Droylesden, engineer. Certain improvements in machinery or apparatus for effecting the separation of impurities from the water employed in steam boilers, and also for effecting the circulation of the said water.

3254. G. Lewal, 74, St. George's-road, Pimlico, gentleman. A hot-air apparatus in cast-iron or any other metal or substance consisting of prismatic tubes, to be applied to chimnies with flues and heat conduits. (A communication.)

3256. J. Robinson, Liverpool. Improvements in the construction of ships and vessels.

3258. R. Wallis, Basingstoke, corn and coal merchant. Improvements in apparatus for loading and unloading vessels and transporting sacks, casks, and other packages or parcels from one landing-place or stage to another, or to or from one warehouse to another.

3260. T. G. Webb, Manchester, flint glass manufacturer. Improvements in the manufacture of articles of pressed glass.

PATENT ON WHICH THE STAMP DUTY OF £100 HAS BEEN PAID.

2785. P. A. le Comte de Fontainemoreau.
2894. J. Murdoch.

NOTICES OF INTENTION TO PROCEED WITH PATENTS.

From the *London Gazette.*

2134. W. Maugham. Manufacture of effervescent beverages.

2170. E. F. Prentiss and R. A. Robertson. Obtaining products from rock oil, coal, coal tar, and other like mineral substances.

2185. C. H. Plevins and H. Rider. Construction of colliery waggons, tubs, or corves.

2187. T. G. Webb. Manufacture of flint glass.

2194. A. and E. M. Denny. Manufacture of bacon.

2196. J. Thoma. Self-adjusting screw wrench.

2202. A. Priestley. Arrangements or apparatus applicable to locomotive railway engines and carriages.

2203. W. W. Burdon. Reducing wood fibres to pulp.

2208. J. H. Johnson. Construction of armour plates. (A communication.)

2212. F. H. M. C. D. C. de F. de Lacombe. Lighting and ventilating.

2217. B. Coombe. Apparatus or machinery for cleaning and decorticating.

2223. N. J. Amies. Manufacture of bearings, "journals," and "steps."

2227. J. Tatham. Apparatus for preparing, spinning, and weaving fibrous materials.

2235. T. De la Rue. Manufacture of pigments and writing inks.

2239. W. E. Newton. Compressing powder for cartridges. (A communication.)

2243. N. J. Amies. Manufacture of bearings or stops.

2244. J. Lancelott. Manufacture of ornamental chains from sheet metal.

2246. W. Gedge. Construction of ladders. (A communication.)

2257. A. Delrue. Preventing and removing incrustation in boilers.

2263. G. Sanders. Fire escapes.

2271. W. L. Boyle. Construction of chairs and footstools.

2277. W. Schnell. Extracting the sulphur and sulphurous acid from the oxy sulphuret of calcium. (A communication.)

2278. J. H. Johnson. Carts and other vehicles. (A communication.)

2290. C. E. Spagnoletti. Apparatus for signalling trains on railways.

2300. A. Shepard. Obtaining light.

2306. R. Barclay. Chronometers and other time keepers.

2313. F. Barnett. Lamp or lantern for street lighting.

2347. R. Harrington. Umbrellas and parasols.

2349. D. Moore. Breech-loading firearms.

2351. D. Moore. Revolving firearms.

2382. A. V. Newton. Machinery for printing from engraved plates. (A communication.)

2390. E. Lachenal. Gas meters. (A communication.)

2484. J. Saunders. Lamps.

2485. J. Saunders. Railway break.

2772. E. H. C. Monckton. Coils of induction, and in obtaining and applying power by means of electro-magnetism.

2848. T. Fearn. Manufacture of rods, poles, tubes, and other forms employed in the construction of various articles of furniture.

2857. M. C. A. Perkes. Revolving rudder. (A communication.)

2908. A. Shanks and F. Kohn. Hydrostatic presses.

2928. G. Mayall, jun., and J. Hollingworth. Apparatus for preparing fibrous materials for spinning.

2934. A. Guild. Preparing and treating the leaves and stalks of fibre yielding plants.

2942. C. Gubbins. Irons for ironing.

3066. E. S. Cathels. Manufacture of gas.

3111. J. B. Edmondson, J. Carson, and J. Blaylock. Printing, numbering, and dating railway and other tickets.

3160. E. Wadsworth. Manufacture of braid.

3198. W. E. Gedge. Clocks or time-keepers. (A communication.)

The full titles of the patents in the above list can be ascertained by referring back to their numbers in the list of provisional protections previously published.

Opposition can be entered to the granting of a patent to any of the parties in the above list who have given notice of their intention to proceed, within twenty-one days from the date of the *Gazette* in which the notice appears, by leaving at the Commissioners' office particulars in writing of the objection to the application.

LIST OF SPECIFICATIONS PUBLISHED

For the Week ending December 19, 1862.

NOTE.—Specifications will be forwarded by post from the Great Seal Patent Office (publishing department) on receipt of the amount of price and postage. Sums exceeding 5s. must be remitted by Post Office Order, made payable at the Post Office, High Holborn, to Mr. Bennet Woodcroft, Great Seal Patent Office.

THE MECHANICS' MAGAZINE.

Contents of the Last Number:—

THE
MECHANICS' MAGAZINE.

LONDON, FRIDAY, DECEMBER 26, 1862.

ON THE FUSION OF STEEL IN LARGE MASSES.

AT a recent meeting of the Paris Academy of Sciences, Monsieur A. SUDRE read a paper on some experiments for this purpose made on an extensive scale by the orders and at the expense of NAPOLEON III. These trials were conducted at the Montataire iron works during the months of November and December, 1860, and January, 1861. The new process consists in melting any given kind of steel on the concave hearth of a reverberatory furnace. The furnace is heated by coal, while the steel is protected from oxydization by a bath of slag or scoria. This slag must answer to the following conditions:—It must not exercise any decarburizing influence on the steel, nor must it corrode the bottom or sides of the furnace. These conditions are fulfilled by the silicates of earthy bases, such as either the slags extracted from charcoal smelting furnaces, or common bottle glass. These substances can be obtained anywhere cheaply, or they can even be prepared in the melting furnace itself. The following are the results of operations that have been carried out in masses of 600 kilogrammes (nearly 12 cwt.) at once, and under the supervision of competent judges:—

1st, Even soft steel is found to melt easily under the slag covering. This is the fundamental point, *a priori*, the subject of much discussion; 2nd, the quality of the steel remains unaltered by the process; 3rd, slightly carburetted steel is found to melt in four hours, with a consumption of two parts of coal to one of steel, a consumption of fuel probably subject to future diminution; 4th, the same slag is found to answer for several successive meltings; 5th, the running out takes place with ease, as also regularly and continuously; 6th, a furnace made of good ordinary firebrick lasts eight days, corresponding to about thirty meltings.

The process is said to afford the following advantages:—1st, it does away with crucibles; 2nd, it causes a great saving in hand labour, and saves the workmen much painful and dangerous toil; 3rd, it reduces the consumption of fuel; 4th, it affords the means of fusing two or three thousand kilogrammes (nearly two to three tons) in the same apparatus; 5th, it offers a means of obtaining steel of any required quality and hardness, a very important advantage in the steel manufacture; 6th, the saving is reduced to two-thirds of that of the usual process. In France the expenses of melting in crucibles come up to about 150 to 200 francs per ton. The melting in a reverberatory furnace will not cost more than 60 francs, and this price can be still further reduced; and the cost of the apparatus for carrying out this plan is much less than with the ordinary process in which crucibles are used. All these advantages, distinctly proved by trials on several hundred kilogrammes at a time, seem to stamp it as a practical manufacturing process.

Mr. Frémy, well-known for his works on steel, who was present at this sitting of the Academy of Sciences, observed, that M. Sudre had rendered a great service to industry, if he had really solved the problem of melting steel in large masses. He could, however, express no opinion on the matter, not having been present at the trials.

M. H. Sainte-Clare Deville (who first produced aluminium in large quantities), observed, that he himself had seen 600 kilogrammes of steel melted at one time. It is very probable that Napoleon, in making these experiments, had in view to use this steel for large ordnance. "Notre ami l'ennemi," does not neglect details. The Austrians know only too well how "details" helped him to conquer at Magenta and Solferino.

IRON PLATED SHIPS AND PROJECTILES.

THOUGH the vast question of armour-plated ships is necessarily in a state of transition, there is no pause in their construction in America, France, or England. Since Mr. Whitworth sent explosive projectiles through five-inch iron plates, ships built on the "Warrior" principle have been at a discount. What Mr. Whitworth can do a foreign Government can do; and should an engagement take place, a French man-of-war, armed with Whitworth guns and projectiles, would make short work of either of Admiral Stuart's squadron, including the "Warrior," "Black Prince," "Resistance," and "Defence," which behaved so "wonderfully" during their recent cruise between Lisbon and Gibraltar. It is very encouraging to know that all these vessels have proved themselves to possess "excellent weatherly qualities." The admiral, it appears, determined to test the ships in every possible way, and each is described as being admirably handled. So far so good. But if they can be riddled with Whitworth explosive projectiles, their "weatherly qualities" would avail them but little. If our artillerists could merely make holes in iron-clad ships, the evil might be remedied, to some extent at all events, by plugs. But what good would be plugging up a hole when the destructive missile is lodged somewhere *in* the ship. Mr. Whitworth, by his recent achievements, has made himself, as the French would say, master of the situation. His gun may not be all that it is painted. It may occasionally burst, to the evident discomfort of the artillerymen. Rapid firing of the gun may derange its inner surface. Even Mr. Whitworth may not be the sole inventor, either of the gun or of his projectiles, as more than one of our contemporaries have taken considerable pains to show. But, after due allowance is made for all these objections, it cannot be denied that Mr. Whitworth has established facts which have shaken the faith of our Admiralty Lords in the invulnerability of iron ships. We await, however, with considerable interest, further Whitworth and Armstrong experiments.

In the meantime the Admiralty are going on building ships; possibly, when they are built, they will be found next to worthless. During the last session of Parliament we heard a great deal about Capt. Cole's cupola ships. Money was voted, and preparations were made for the construction of, we believe, two ships on Capt. Cole's principle. We should be glad to know what progress has been made in this direction. Is the gallant captain as hopeful as ever? Is he developing his idea slowly and surely, with the intention of startling us some fine morning with a magnificent success? Whatever progress is being made, whether slow or fast, we at all events hear but little about the construction of cupola ships.

Mr. Reed, it appears, is making "rapid progress." The "Enterprize," under his superintendence, in Deptford Dockyard, is in an encouraging condition. The planking of the bottom is now completed, and the false keel has been filled and coppered. The deck of the battery platform, and the deck above the battery, are being laid, and the timber portions of the ship, we are informed, are rapidly approaching completion. The form of the "Enterprize" appears to be much admired, and it it is predicted that she will possess excellent qualities as a sea-going ship. Officers of the Ordnance Department have surveyed the ship, for the purpose of arranging the details of the armament, and have found that ample accommodation has been afforded for four Armstrong 110-pounders, even when mounted upon carriages and slides of the largest kind. So far, then, the vessel bids fair to be much superior to ships built on the cupola principle, which are intended to carry only one gun each. But is the "Enterprize" to be fitted with Armstrong guns? We must say we paused and rubbed our eyes on seeing this announcement. We always considered Mr. Reed a staunch opponent of the Armstrong gun, and he has earned the reputation of saying the strongest things against it. Has Mr. Reed changed his opinion on the efficiency of the Armstrong system of artillery? Sir William has not been in the ascendant of late. In fact, Mr. Whitworth, in the minds of all unprejudiced persons, has distanced him in the race of gun-making. It is, therefore, not at all likely that Mr. Reed thinks more of the Armstrong gun now than before the "Enterprize" was commenced. If not, why does he permit himself to be imposed upon by officers from the Ordnance Department? Is it for the sake of peace and quietness he is so submissive? Or does he say that he has nothing to do with the character of the guns the "Enterprize" is to carry? Mr. Reed should certainly, we think, have a voice, to say the least of it, in the selection of guns for the "Enterprize." He has either interfered in the matter, or he has not. If not, then, unless he has changed his opinion, he is winking at the perpetration of a wrong. If he has told the Admiralty his opinion, then is his voice overruled by the "officers appointed by the Ordnance Department."

Several inventors and others, including Mr. Reed and Capt. Coles, have submitted plans to the Admiralty for cutting down our large men-of-war and planking them with iron. We have, some time since, commenced this "reconstruction of the navy." As we appear to be influenced to a great extent by what the Americans do, and endeavour to profit by their experience, it is not improbable that we should pause now that the American iron-clad vessel "Eastport" has proved a failure. This vessel was taken by the Federals from the Confederates. She has since been thoroughly mailed, but her keel was too weak, and the weight of metal put on her broke her back. The failure of the vessel, says an American paper, is a trifling matter compared with the principle it apparently involves. The "Benton," another Federal iron-clad vessel, has also failed from a similar cause. It would seem that an exclusively wooden vessel cannot be mailed heavily, and retain her buoyancy and usefulness. If wooden vessels are so susceptible of destruction by plating, an important point is settled, as the converting of old frigates and liners into iron-clads must cease. Possibly the "Eastport" and "Benton" were radically weaker than our substantial frigates; if so, her failure should only lead to enquiry and experiment. Enquiry and experiment should always precede important changes, instead of succeeding them, as is frequently the case in this country. We act first and learn afterwards, instead of learning first and then acting.

We will conclude these discursive observations with a word or two on the fouling of iron ships. It is well known that, when copper and iron are placed in contact, galvanic action takes place, and the iron soon gets destroyed. The greatest disadvantage that iron ships have to contend with is their liability to become foul. Hence, the many inquiries which have taken place, and the many inventions which have been patented to protect the hulls of iron ships from fouling. Various preparations for the purpose have been applied in this and other countries, and we have from time to time called attention to new inventions and new suggestions on the subject. A short time since H.M.S. "Triton," which had been coated with a preparation of copper, had, after a voyage, to undergo a scraping, and tons of oysters, barnacles, &c., were removed from her bottom. During the process of cleansing, the scrapers actually rubbed through the iron plates, so completely had they been destroyed by galvanic action. We now learn that the French ship, "Le Gloire," which had lately been examined, is in a similar condition. All the iron plates under the water line will have to be removed, as they have been converted into something like plumbago by galvanic agency. This circumstance will no doubt call the attention of the French Government to the subject; and perhaps the nation which first adopted iron war ships will also first invent some mode to prevent them fouling.

THE EFFECTIVE DISCHARGE OF PUMPS.

In our present number, page 415, will be found the results of an examination, by Mr. Zerah Colburn, C.E., into the useful effect of the two principal centrifugal pumps that figured in the late Exhibition. Without further alluding to this interesting paper, it will be at once seen that one of those two centrifugal pumps gives a remarkably high per centage. This one is working at a speed, in fact, nearly double as high as the other. We are inclined to hazard the opinion that the more continuous and equable current thus produced will somewhat account for the difference between the performance of the two pumps.

In the Jury report of the special committee on fire-engines, a very remarkable fact is shown in the tables of the trials. In some instances, there is actual gain over and above that due to the cubic contents of the pump itself. In one case, this was as much as 14 per cent. It is as well to state that the special Jury have not given the power expended in working these fire-engines; they have only stated the number of men at the handles. In our experience in mining pumps, we have noticed a similar case in relation to a 12 in. diameter "draw lift."

This remarkable fact is probably due to the quick current of water through the clack valves; this current keeping the valves open even when the bucket or plunger (as the case may be) is stationary. It appears to us that the importance is often overlooked of arranging pumps in general, and double pumps in particular, in such wise that the stream of water is as continuous as possible.

There was a double pump in the western annex in the Exhibition, sent by Messrs. Farcot and Sons, of Paris, that appeared to obtain a continuous stream in a very simple, and, as we believe, rather original manner. As far as we could make out, in the absence of drawings, this double pump appeared to consist of two equal pump buckets, working *parallel* to each other in two cylinders.

The two buckets being moved up and down together, the first bucket draws in water by its upper surface, and then causes it to pass through the second bucket. In going up, the second bucket raises the column of water by its top surface, and the lower surface sucks the water through the first bucket. We have even seen it proposed (but feel rather doubtful as to its realization) to work a common reciprocating pump at a high speed, and thereby cause a continuous flow of water through the pipes after once the action was begun. In this case, "*Est le premier pas qui coute*," as the French say. As is well known, the loss in useful effect of reciprocating pumps, caused by the leakage of the clack valves, is often more than 1-10th, although this may be much diminished if these parts be kept in good working order—a fact which may also help to account for the surplus water delivered at the fire-engine trials in Hyde-park, on the 1st of July last, the engines tried being newly made. The minimum of loss answers to a fixed speed of piston, varying according to the state of the pumps or their construction. According to D'Aubuisson, the loss by the leakage of the clack valves is in an inverse ratio to the length of the stroke of the bucket or plunger. A badly-packed or worn away bucket lets the water fall back; badly-fitted clacks do not shut tight, or do not open and shut at proper times. It is very important that the stroke of a pump, a large one especially, should, by a short stoppage, give time to the valves to open and shut. If the piston has to drive down the clack, the sudden closing causes a reaction of the column of water, and the higher this column is, the greater the percussion of the valves on their seats. We believe that the plungers of the large pumps in Cornwall work at the rate of about seven to eight strokes per minute, rising at the rate of about 260 to 280 ft., and descending at the rate of 85 ft. per minute.

II.

FRENCH SUBMARINE CABLES.

Schiller makes one of his characters say, "It is wise to take good counsel before sailing out of the safe harbour." As the Atlantic submarine cable adventure is on the *tapis*, it will not be amiss to look around us and see how other nations have fared with similar enterprizes. According to the French papers, the communication of the cable between France and Algiers has been somewhat interrupted, after working with tolerable success for about a year. The communication is broken between Algiers and the Balearic Isles; it is supposed about 240 miles from the town of Algiers, in the middle, therefore, of the Mediterranean. *Le Moniteur Universel* informs us that a Government vesssl has been sent out to raise the cable, which it has already done to the extent of several miles.

A short account of the Algerian cable will not be devoid of instruction. It was, in the first instance, laid direct, without any intermediate station, between France and Africa. This was done in the young and palmy days of submarine telegraphic engineering, when the self-confidence of its youth caused it to oversee difficulties, and to disbelieve in the word impossible. This arrangement, as is well known, proved to be a failure as sudden as it was complete, and the line was then made to touch at the islands of Sardinia and Corsica.

After working for some months with great irregularity (an irregularity so great that telegraphic despatches were often received *after* the explanatory written letters), the cable in the end refused to speak at all. It was then seen that it would be safer to make it touch at the Balearic Isles, and with great difficulty the cable was again fished up for this purpose. The cable thus laid has, in its turn, also suddenly refused to act. The French scientific press now advises the telegraphic administration to take the line over Spain, and from thence to choose the shortest route to Algeria, or it could even be taken over Gibraltar, and along the coast of Morocco. The French papers say that, "if the Sultan of Fez has not the power to protect the line thus carried along his coast, this could be done by the French Government. This would also be a double gain, as the pirates of Riff could be watched by the same means."

Truly enough, submarine cables ought to be protected by international law. No civilized nation would refuse its signature to such a treaty. *La Presse Scientifique* criticises the apathy of those men of science who did not use the telegraphic cable when it existed to take simultaneous astronomical observations. It concludes with an irreverent sneer at the "common-place messages to be found in any Mass-book" (*sic*) we Anglo-Saxons transmitted during the short existence of the Transatlantic cable. It also translates the sublime message that passed between England and America by "Peace to the well-disposed men of the earth!" This is something like the story of the Frenchman translating "The Green Man and Still" into "*L'homme vert et tranquille!*"

II.

INTERNATIONAL EXHIBITION.
JURORS' REPORT.

(Continued from page 401.)

Class X., Section A.—Civil Engineering.

In the space beneath the caisson compressed air was used to expel the water and to allow the men to work, and it was also employed to force down the cylinders to the requisite depth, the air pumps being worked by a steam engine from above. Within the caissons workmen were employed to remove the gravel, &c., from under the exterior edges as they descended, whilst the great mass of the material, which was cast by hand to the centre, was removed by means of the dredging apparatus worked by a steam-engine upon the platform above. The novelty and the chief cause of the efficiency of this apparatus consisted in the centre cylinder being open to the atmosphere at the upper extremities, and plunged in the water at its lower end, by which means the great mass of the material could be removed by the dredging apparatus much more rapidly and economically than if all the material had been hoisted in buckets through the air-locks, in the usual closed cylinders. The caissons were thus carried down to the requisite depth below the ordinary level of the Rhine most successfully, in a much shorter time, and at infinitely less cost than by the usual method, and the piers were founded at such a depth below the scour of the current, as to give every reasonable guarantee of their stability. The superstructure, which was executed under the supervision of M. Keller, the engineer-in-chief, and the Baron Kagenech, engineer of the Grand Duchy of Baden, does not offer any remarkable features, although it has been well executed and perfectly answers the purpose for which it was intended. To M. Vuigner, chief engineer of the Eastern Railway Company of France, and M. Fleur-Saint-Denis, engineer of bridges and roads, and author of the project, have been awarded a collective medal, for the ingenuity of design for these piers and foundations; and to Messrs. Castor, the contractors, also a medal, for the intelligence of their arrangements and the successful execution of this work, and also for a similar application at the bridge of Argenteuil.

The next bridge worthy of mention is that over the Garronne, at Bordeaux, to connect the Orleans Railway with that of the South on the

other side of the river. This extensive work was originally designed by the late M. Alfred Bommart, engineer-in-chief of bridges and roads, and it was after his decease carried into effect under the direction of M. Surell, engineer-in-chief of bridges and roads, by the enterprising contractors, Messrs. Pauwels and Co., under the superintendence of M. De la Roche-Tolay, engineer of bridges and roads, chief engineer of the company, and M. Regnault, engineer of bridges asd roads, resident engineer. The total length of this bridge is 500 metres, and it consists of seven openings, the two extreme spans being 57½ metres each, and the five other spans 77½ metres from centre to centre of the piers.

The superstructure is formed by wrought-iron girders upon the trellis principle, which require no further remark, than that they are well executed. The foundations of the piers were executed by means of cast-iron cylinders, which served as air chambers, having the air lock on a platform attached to the upper part of each cylinder, and which was removed, as occasion required, to replace another length of cylinder. These cylinders were sunk in pairs, side by side, by the compressed air system of M. Triger, and the pressure was given to the cylinders by hydraulic presses. The bed of the river was composed of mud and sand, through which the cylinders were forced, with a depth of water varying from 7 to 13 metres, a current of from 2 to 3 metres per second, and a strong tide rising 6 metres. These were some of the difficulties to be contended with, and which were very successfully overcome by the intelligent foresight of the engineers and the practical experience of the contractors. To MM. A. Bommart, De la Roche-Tolay, and Regnault, the engineers, has been awarded a collective medal for the boldness of the design, and the simplicity and economy of construction of this bridge; and the same recompense has been also awarded to Messrs. Pauwels and Co., the contractors, for their intelligence in carrying into effect the designs of the engineers, and more especially for improvements in the application of hydraulic presses for forcing down the cylinders, on the system invented by Messrs. Fortin-Hermann and Co.

In addition to the above bridges, or viaducts, there are models of several others, of which the superstructure, piers, and abutments, are of masonry. The bridge at Chaumont, by M. Decomble, engineer of bridges and roads, although displaying nothing original in the design, or construction, is well executed, and is creditable to the engineers and contractors by whom it was designed and constructed.

This important work, which is nearly 700 metres in length, 53 metres in height, was constructed in 14 months; its execution is perfect, and the general effect is very good. To M. Decomble, the engineer intrusted with the execution of the work, has been awarded a medal; and to Messrs. Parent and Shacken, contractors, and Monsieur Gourdin, their engineer, honourable mention for their intelligent co-operation and the excellent arrangement of their executive staff.

The viaduct of Nogent, on the line of railway from Paris to Mulhouse, consisting of three arches, each of 50 metres span, and of 30 arches each of 15 metres span, all in masonry, deserves mention, as a well-designed and excellently-executed work, for which honourable mention was awarded to M. Pluyette, engineer of bridges and roads, intrusted with the execution of the work.

The bridge of Napoleon, at St. Sauveur, in the Pyrenees, consists of one semicircular arch of 42 metres span in masonry. The foundation presented great difficulty in consequence of the mountain torrents swelling the course of the Cave de Pau. To M. Marx, engineer-in-chief of bridges and roads, and to M. Bruniquel, resident engineer, were awarded collective honourable mention for the good execution of this boldly-conceived work.

There must also be mentioned the successful execution of a large bridge over the Vistula, near Dirschau, designed by M. Lentze, for which, and for the ingenuity of the inclined planes on the Oberländische Canal, designed by M. Steenke, medals have been awarded to the Minister of Commerce of Berlin, and to the Royal Engineer Works at Dirschau (Zollverein, 1,338). To Messrs. Schnirch and Fillunger (Austria, 626), for the bold and successful bridge over the Danube Canal at Vienna, and to the State Railway Society (Austria, 628) for their good structure, introducing improvements by Rupert in lattice bridges, and for the excellence of execution of these and other important works, medals have been awarded.

To Messrs. Klett and Co., of Nuremberg (Zollverein, 180), a medal has been adjudged for the boldness of the design and the successful execution of the railway bridge across the Rhine, at Mayence, on the system introduced by M. Pauli. This bridge has a very large span, and is of singularly simple construction, offering great facilities for repairs and for keeping in order, by painting, &c., all parts being accessible.

To the Commissioners of New Brunswick was awarded honourable mention for the utility of the bridge works, of which models were shown.

II.—HARBOURS AND DOCKS.

WITH regard to this department there are several works particularly worthy of notice; and amongst the most important must be mentioned the great "digue," or breakwater of Cherbourg. The history of this great work is very remarkable, and the structure itself presents a great variety of operations, equally instructive from their failure and their success. There have been tried here consecutively the ingenious yet abortive dea of the wooden cones filled with small rubble stone—the small rubble upon the *pierre perdu* system, which was equally unsuccessful—then the larger rubble system—and finally the béton and masonry systems, by means of which this great work has been eventually completed. All these plans exhibit considerable ingenuity and skill; nevertheless, it must be admitted that the construction of this great work, at the outset, evinced great deficiency in the knowledge of those first principles which should guide the engineer in the construction of works of this nature and magnitude.

The breakwaters of the Carthaginians at Tyre and Sidon, of the Greeks at Athens, Halicarnassus, Ægina, and in numerons other places, as well as those of the Romans at Ostia, Civita Vecchia, Ancona, Naples, and other ports in the same vicinity, show that the simplest and most economical mode of constructing barriers, or breakwaters, to resist the violence of ocean storms, was by throwing down, or depositing, rough undressed blocks of stone, as raised from the quarries, and allowing them to form their own slope, or inclination, by the action of the waves, until finally the masses, thus thrown down, become settled, when their permanence was further augmented by the growth of seaweed and the drift of the sand into the crevices; so that these works have remained unaltered until the present day. The experience, however, derived from these works does not appear to have been taken advantage of until within a comparatively recent period, and hence the variety of systems introduced in the construction of the breakwater at Cherbourg. In fact, instead of starting from the point of demonstrated success, a comparatively tentative process would appear to have been pursued; whereas, if the knowledge of the past had been taken advantage of, much trouble and cost would have been avoided.

It is to be regretted, in an engineering point of view, that the position of the breakwater should have been determined by purely military considerations, which demanded a direct line between the forts Pelee and Querqueville, thus materially reducing the extent of the roadstead.

The history of this great work, as given in the works of M. de Cessart and MM. Alexis de Tocqueville, Cachin, and Bonnin, &c., as well as in the "Annales des Pontset Chaussées," conveys much information. Due honour should be given to the several able engineers-in-chief and to their subordinates, who have brought the work up to its present satisfactory state. The names of the chief engineers are:—

Captain la Bretonniére, Royal Navy, 1777 to 1782.

M. de Cessart, inspector of bridges and roads, 1782 to 1792.

M. Lamblardie, inspector-general of bridges and roads, 1792 to 1793.

When an interval occurred until 1802, when the works were resumed.

Le Baron Cachin, inspector-general of bridges and roads, 1802 to 1823.

M. Fauques Duparc, divisional inspector of bridges and roads, 1823 to 1838.

M. Reibell, inspector-general of bridges and roads, 1838 to 1853, when the work may be said to have been completed, and to the latter eminent engineer and his able coadjutors, MM. Virla, Mahyer, and Bonnin, engineers of bridges and roads, and to their predecessors and assistants, a collective medal has been awarded, on the completion of this important work, after so many years of persevering efforts, due to the judicious use of all the resources induced by the progress of marine construction.

It is not any detraction from the merit of the many able engineers who have been employed upon this great work, to say that every allowance must be made for the want of knowledge and experience which existed at the time when it was commenced; and as a matter of scientific inquiry, it is most interesting to place on record all the facts of the progress, and to compare the modes employed with those of the present day.

The new port of Marseilles is a great work, which has been planned and executed upon an extensive scale by M. Pascal. engineer-in-chief of bridges and roads. It is situated to the eastward of the old natural harbour, formed by a creek, which was taken advantage of, and around which the town sprung up. The new artificial harbour consists of a series of wet docks, or basins, formed by moles, or breakwaters, constructed in the open sea. They run parallel to the shore, and communicate with each other by openings and locks through the cross walls which separate them from each other. The outer, or boundary sea wall, connecting the whole system, answers the double purpose of a breakwater on the outside, and a quay wall on the inside; and at each end of these docks is an outer, or entrance harbour, so that vessels can use either, according to circumstances, and can pass from one to the other, as convenience may require. There is, also, a connection with the old harbours. The general design of this harbour is good, but the sea entrances are scarcely sufficiently protected against the swell of the sea during storms. The details of the construction are entitled to considerable credit, for every class of materials has been utilized to the greatest extent; the smallest stones being used in the interior and the largest in the exterior, where the face is exposed to the greatest action of the sea. The outer face, or sea slope, of the great exterior breakwater is protected by large masses of béton, formed into artificial blocks, each weighing from 25 to 30 tons, which are said to be immoveable by the most violent action of the waves; and so far they have resisted the disintegrating effects of the sea, and the atmosphere and with success, although further experience is necessary, before the béton masses can be pronounced to be indestructible. Great credit is due to the French engineers, amongst the earliest of whom may be mentioned M. Poirel, for reviving this ancient system of building, and to M. Pascal, the engineer-in-chief, the award of a medal is made for the methodical and scientific direction of these important and extensive works, including the utmost economy, without sacrificing the excellence of construction, and to Messrs. Dussard, Brothers, of Marseilles, the contractors, honourable mention for their intelligent assistance in the execution of important parts of the works.

The lock-gates of the docks, at the port of St. Nazaire, are specimens of timber constructions of very large dimensions, not requiring the use of any logs of large scantling; and M. Watier, engineer of bridges and roads, the author of the design, and the constructor of the first gates on this system, to whom honourable mention has

been awarded, is entitled to great credit for the boldness of the design and the ingenuity of the construction, in which he was strenuously supported and succeeded by M. Leferme, engineer of bridges and roads. The general works of the port being first under the direction of M. Jegou, and subsequently under M. Chatoney, engineers-in-chief of bridges and roads.

The lock of the citadel and the graving dock of the Eure basin at Havre are important works. The graving dock and its entrance locks are designed upon a very large scale, with the view of receiving the vessels of heavy tonnage engaged in the trade with New York; the depth of water on the cill being 8½ metres at low water of spring tides, and the locks being 30½ metres in length. The construction of the walls is of the best quality, and much ingenuity has been exhibited during the progress of the works, as well as in the general designs for the extension of the port of Havre, for which there has been awarded a collective medal to M. Bouniceau, engineer-in-chief of bridges and roads, and to MM. Bellot and Lemaitre, resident engineers.

(*To be continued.*)

THE ATLANTIC TELEGRAPH.

The above incline of 1 in 6 is the steepest gradient that has been proved to exist in the ocean bed *on the* line adopted in 1858, by the Atlantic Telegraph Company, for laying their cable between Valencia and Newfoundland. Yet parties interested in rival localities and competing lines have not hesitated to describe this gentle slope as a "*precipitous clift*," and as unsafe and unsuitable for laying a cable, although the bottom has been shown to be formed of the softest ooze, in comparison of which the finest sea sand might well be called rough and rugged.

TO THE EDITOR OF THE "MECHANICS' MAGAZINE."

SIR,—The above sketch appears to me the most concise way of refuting a misrepresentation which has been very industriously circulated, regarding the telegraph line between Valencia and Newfoundland, and I place it at the head of this letter, which I would beg of you to insert as a reply to one which appeared in your paper of the 20th ult., from Professor King, of the Queen's College, Galway.

In undertaking to point out the best place for landing an Atlantic cable, Professor King appears to have totally misapprehended the principles essential to guide us in such a selection; and when he proceeds to point out the merits of one line, and the demerits of another, as resting places for the cable, he is not always correct as to details, and when accurate, the reason he gives for his preference are often trivial and inconclusive.

It may appear presumptuous in me, who am not a man of science, to speak thus; but I have taken so much interest in this question from its commencement, and I have come into contact with so many of the acknowledged leaders, scientific and practical, of the telegraph undertaking, that I feel tolerably strong on the subject, and I hope not to advance any opinion that cannot be maintained; at any rate, I cannot be mistaken as to the principles which governed the promoters of the Atlantic Telegraph, in selecting their line and their landing-place, and which ought, I feel certain, to guide any persons engaged in a similar undertaking.

The first consideration, where the distance was inevitably so great, would naturally be to make their ocean line as short as possible, and with that view, to select the points at either side of the Atlantic, which, being otherwise suitable, were nearest to each other. They would next proceed to ascertain whether the line connecting these two points was suitable; requiring not only that the ocean-bed should be fit for the reception and preservation of a cable, but that water of considerable depth should continue up to the landing-place, which should be on a shingly or sandy beach. They would further require that the cable should lie as free as possible from all risk of injury by anchors of vessels or trawls of fishing boats; and lastly, they would desire, though not absolutely essential, that the landing-place should be in or near a good harbour, for greater facility in laying the cable, and, if necessary, in under-running it.

Now, I can say, without hesitation, that not one of these requirements has been lost sight of by the promoters of the Atlantic Telegraph, and that every one, without exception, has been secured by their selection of Valencia.

On the other hand, how does Professsor King appear to view these principles? As to the first, he must be aware that Galway is 62 miles further from the opposite shore of the Atlantic than Valencia; he, therefore, would ask the company to add to their already sufficiently arduous undertaking* 62 unnecessary miles of cable, of which a considerable proportion must be of the heavy or stone-end description, costing £400 per mile. But the expense which this involves is but a small part of the burden which it would throw on the company. The greater part, if not the whole, of the extra miles of cable, would be laid in ground where it would be peculiarly exposed to injury from anchors of drifting vessels, and trawls of fishing craft; in fact, the most dangerous, in this respect, which could be found in the whole of the west coast of Ireland. He would thus needlessly imperil, not merely the value of this extra cable, but, in truth, the whole of the vast capital invested in this great undertaking. We have all heard of "*going further and faring worse*" as an operation to be avoided, but to find it deliberately recommended, where such interests are involved, is not a little surprising.

Again, admitting for the moment that the Professor makes out, as a result of the recent soundings, that a good ocean bed for the cable can be found in a line directly west from Galway, he entirely overlooks the other equally essential requisites. He deliberately brings the cable into ground most liable (as I have shown) to danger from anchors, and then makes it land through what he properly calls "*foul ground*," which he further describes as "*hummocks of granite and syenite*." If I did not see it in black and white, I could hardly believe that any one could make such a suggestion, and then go on to assert that for the Galway cable this rocky ground would not only "*not be injurious*," but would be "*advantageous*." Why? Because the cable would thereby escape danger "*from trawling and fishing lines and anchoring of vessels*,"—that is, being aware of having brought his cable into the most dangerous ground on the whole coast, he is obliged to escape from this Scylla into a Charybdis of "*granite and syenite rock*."

So far as to the general principles on which Professor King would select a landing-place. Now, as to his reasons for considering the line from Valencia to Newfoundland less desirable than that from Galway, they appear to me to be four. 1. That the line from Valencia, till it descends to the deeper ocean-bed, is less gently undulating than that from Galway to the same parallel. This may, very possibly, be true, but certainly not to the extent claimed by the Professor, for he charges against the Valencia line a sounding of 525 fathoms, which exceeds by over 100 fathoms anything shown in that region by the Admiralty chart, in the line sounded for the telegraph by H.M.S. "Cyclops;" but admitting, for the sake of augument, his 525 fathoms, what does that involve? Merely the paying out of a few extra hundred fathoms of the lighter description of cable, say, at the outside, a cost of £100 to £150. Against this the Professor will have to debit the Galway line, with the 50 or 60 extra miles of cable, with all the continental evils which I have already pointed out.

2. He states that the dip on the Valencia line, into the deeper ocean-bed, is more rapid than in the other line. Now, even if this were proved to be true, it could not be considered a matter of serious moment, unless it were shown that the slope is very much steeper than anything that has yet been ascertained; but I must altogether question the fact the Admiralty chart shows, a sounding of 1,240 fathoms, nearly due west of Valencia, which, being less than is found on the same parallel west of Galway, would lead to an exactly opposite conclusion.

3. He asserts that the Valencia line crosses two valleys, one of half a mile, the other of three miles in depth. Again, I must question this assertion. I distinctly remember that the deepest sounding found by the "Arctic" was 2,100 fathoms, and by the "Cyclops" 2,424 fathoms; but if even they had attained the depth he claims of 2,640 fathoms, this would not prove a "*valley*" which is generally defined as a "*hollow between hills*," and which was not found either by the "Arctic" or "Cyclops."

4. Assuming a "*valley*" of this depth, he supposes the "*eastern side*" of it to be rocky, from the presence in the soundings of a shell called "*discina, which lives fixed to stones*," and he talks of this as a "*difficulty*." Now, it strikes me that, if these shells came up from the bottom in an appreciable state, the bed cannot fairly be considered "*difficult*" or dangerous for a cable. But surely the Professor must have forgotten having said, a few sentences before, that it was "*advantageous*" to the Galway line that the cable should land through "*hummocks of granite and syenite*;" and he will find it hard to explain how the certainty of rock in shallow water can be "*advantageous*" to one line, while the remote possibility of its existence, in water of great depth, can be a "*difficulty*" to another.

I think, Sir, I have made out my case, that Professor King has misapprehended the principles on which a landing-place for a cable should be selected, and has shown no good reason for preferring the Galway line; but, in conclusion, I beg to say a word on a point which has no direct connection with Professor King's letter. Only two objections have heretofore been made to the Valencia line—1, The supposed "*precipitous clift*," at about 200 miles from the Irish shore. 2, The nature of the coast (generally rocky and iron-bound) in the vicinity of the harbour, which might be supposed prejudicial to the permanency of a cable. As to the first, the fallacy of the "*precipitous clift*" is sufficiently exposed by the diagram at the head of this letter. As to the second, I can give, not a theoretical, but a very practical answer. The cable was brought to Valencia in August, 1858. It has lain as then placed since that time, and in that interval of four years has endured storms of no ordinary severity. I have recently under-run it in a position (a mile or two outside the harbour) where, if at all, danger might have been expected. I have taken up about a mile of it, and found it in such perfect preservation that, without delay and without any repairing, I have used it as a part of a submarine connection between this island and the main land, and through it we have since telegraphed thrice a day, without a single interruption, the state of our weather to the Statistical Department of the Board of Trade. I hope this may be considered a sufficient proof that the landing-place selected by the Atlantic Telegraph Company was not an unsuitable one.

Apologizing for the length of this letter,

I am, &c.,

P. FITZGERALD, Knight of Kerry.

Valencia, Dec. 13, 1862.

* If, as would appear, Professor King intends to stop at Cushla Bay, "10 miles west of Galway," he would certainly be chargeable with 10 miles less of cable, but he must then provide telegraph connection between Cushla Bay and Galway.

BURSTING OF A FLY-WHEEL.—According to a New York paper, a large fly-wheel, 20 ft. in diameter, at a rolling mill, in Philadelphia, lately burst while moving at the high velocity of 200 revolutions per minute. It was used on machinery for rolling steel plate for saws, springs, &c. A portion of the wheel passed up through the roof of the building. A man was killed. The machinery connected with it was broken to pieces before the engine could be stopped. The velocity of a wheel, 20 ft. in diameter, making 200 revolutions per minute, is over 140 miles per hour.

CENTRIFUGAL PUMPS.

WE have received the following useful letter, addressed to Messrs. Gwynne and Co., of Essex Wharf, by Mr. Zerah Colburn, Civil Engineer :—

MESSRS. GWYNNE AND CO.

Gentlemen,—In accordance with your instructions of the 27th ultimo, I at once examined your engines in the International Exhibition.

The engines and pump were run experimentally on the 29th, 30th, and 31st of October, and on the 1st and 3rd instant (November).

The only trials of your pump, upon the general results of which I am disposed to place much reliance, were those made on the 4th inst.

The trial of greatest interest was to ascertain the efficiency of the pump, both as to the absolute discharge, and as to the proportion which the useful work done might bear to the power expended.

The engines and pump being run continuously at the rate of 200 revolutions per minute, the water in the lower tank fell 1 ft. 9¼ in. below where it originally stood before the pump was started, and the water was raised in the upper tank to a maximum height of 1 ft. 8⅛ in. above the crest of the weir, over which flowed an unbroken stream 9 ft. 8½ in. wide, and 12¼ in. in thickness, as measured over the crest of the weir, and occasionally splashing against a board placed 15 inches above the weir. The water, as it rose in the upper tank, presented a curved surface, the highest point of which corresponded to a maximum lift of 20 ft. 6½ in. above the level at which the water stood at the same moment in the large tank below. It was only the water which rose in, and near the centre of the 30 in. pipe, however, which reached this extreme height. It will, however, be making an ample allowance for the somewhat inferior velocity of the water rising in contact with the inner surface of the pipe, if we take the mean lift of the whole body as 20 ft. 4⅛ in. or to a level of 1 ft. 6⅛ in. above the crest of the weir. The velocity of the water ascending the pipe, altogether 20 ft. long, was rather more than 12 ft. per second, and thus the friction of the water in the pipe (the overcoming of which friction formed part of the true "duty" of the pump) would, by Wiesbach's formulæ (accepted by most English engineers), be equivalent to an additional lift of 4½ in., making the total corrected lift 20' 8¾" = 20.73.

The corrected mean rise of the water above the crest of the weir, 1 ft. 6⅛ in., would be perhaps the least which, under the circumstances could have been expected to give an overflow 12¼ in. thick on the weir itself. Taking the true head as 1 ft. 6 in., the full theoretical discharge, without loss of any kind, would be 5733·22 cubic feet, and as the coefficient to be applied in obtaining the actual dis charge, appears from a great number of experiments, by many and high authorities, to be ·57, the actual discharge would be 3,268 cubic feet per minute. The circumstance is to be mentioned, that a certain quantity of air was mingled with the water, over and above that naturally diffused in water, but no estimate can be formed of this quantity, and the discharge may be set down, therefore, as 91·03 tons, raised 20·73 ft. high per minute, or an actual "duty" of 128·1 horse power.

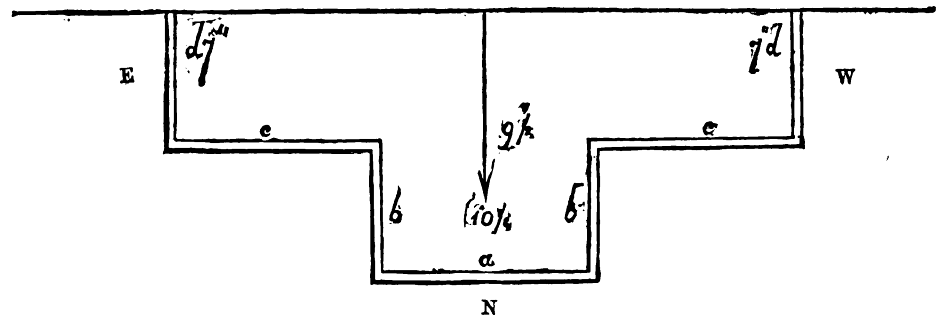
Diagrams, taken at the same time from the engines, showed a mean pressure, exclusive of back pressure, of 26.66 lbs. per square inch. Deducting the ascertained friction of the engines running light, which was 1½ lb. per square inch, and deducting one-seventh of the remaining pressure, as the friction due to the load itself, an estimate made by Pambour, and adopted by Professor Rankine and others, the nett effective pressure usefully exerted in work was 21.56 lb. per square inch, corresponding at 200 revolutions per minute to 154 effective horse power.

Thus the work done by the pump represented 83.18 per cent. of the power actually applied in driving it.

On the 4th and 5th instant, also, in accordance with an understanding between yourselves and Messrs. Easton, Amos, and Sons, I attended to note the working of their engines and centrifugal pump in the western annex. The engines have cylinders nominally bored to 20 (but which are slightly larger), 24 inch stroke, and have a large bevil wheel with 124 teeth on the engine-shaft, which gears into another wheel of 52 teeth on a vertical pump shaft. The diameter of the pump, as given to me by the makers, is 4 ft. 5 in., and the makers, who have had much experience with the working of these pumps, also stated the capacity of their pump in the Exhibition as equal, at 118 revolutions per minute, to a discharge of 100 tons of water per minute on a 6 ft. lift.

The next trials were made to test the absolute efficiency of the pump, both as to the quantity of water raised, and as to the proportion of useful work done to the power applied.

The engines being run at 52 revolutions per minute, corresponding to 124 revolutions of the pump, the total lift of the water was found to be 7 ft. 0⅞ in., or say 7·0833 ft. The rim of the upper tank, over which rim the water was discharged, was of the following shape :—



The total length of the line of overflow, as measured around the inside of the tank, was 42 ft. 1 in.; the northermost inner edge being 6 ft. and ⅛ in. long. The flange forming the edge of tank was 2¼ in. wide all round, and was horizontal on its upper surface. The water entered the upper tank in a horizontal direction, indicated by the arrow on the sketch, and through an opening 5 ft. 10¼ in. wide. The height of the water above the upper edge of the tank, when the pump was making 124 revolutions per minute, was found to be as marked in figures on the sketch—to wit, 9¼ in. in the middle of the larger part of the tank, 10¼ in. in the middle of the fore part, and 7 in. in each of the side bays of the tank. The height of the water over the centre of the pump was 13¼ in. above the edge of the upper tank. The actual thickness of the stream overflowing on the northernmost edge was 8 inches, and on the easternmost and westernmost edges 5¼ in. In calculating the discharge I have, in order to allow for the initial velocity of the water approaching the edge marked *a*, considered the discharge over that edge to be due to the full head over the pump or 13¼ inches. The discharge over the sides *b b* has been calculated, as due to a true head of 10¼ inches, as measured by holding a long straight edge across the tank, and so as to skim the water.

The direction of the current in the tank being parallel to the sides *b b*, the discharge over them would really be somewhat less than that due to the full head of 10¼ in., but I have made no deduction on this account. For the sides *c c* and *d d*, a true head of 7", as obtained by means of the straight edge, is taken. These sides, being out of the line of the current setting through the tank, I have made no allowance for the initial velocity. The true head acting to produce a discharge over the four sides *b b* and *c c* would no doubt be intermediate between 10¼ and 7¼ inches; as for some part of the length of the sides *c c* the head must have been greater than 7 inches. If, however, the mean of these heads, or 8¾ inch, be taken as the true head acting over the four sides *b b* and *c c*, the total calculated discharge would be rather less than that by taking the heads 10¼ inch and 7 inch respectively. With the desire, therefore, of not under-estimating the discharge of a pump, which must be looked upon as a rival of your own, I have adopted the calculation giving the greater discharge, taking a head of 10¼ in. for the whole length of the two sides *b b*, and a head of 7 in. for *c c* and *d d*. The co-efficient of discharge under an equal head, would be considerably less for a weir 2¼ in. wide than for one of ⅜ in., but as there was a less depth of head acting upon Messrs. Easton, Amos, and Son's weir, I have taken the same co-efficient as in estimating the discharge from your pump, viz., 57 per cent. of the full theoretical discharge.

In the case of Messrs. Easton's pump, then, the discharge over the edge *a* was 1319·11 cubic feet per minute, that over the two sides *b b* 1796·31 cubic feet per minute, and that over the four sides *c c* and *d d* 1938·22 cubic feet, making 5053·64 cubic feet per minute for the total discharge. Air was, of course, present in the water, the total body of water falling, and the superficial extent of the falling sheet being much greater than from your pump, although from the low lift the velocity at the end of the fall was probably not more than two-thirds as great as in the case of your pump. As it is impossible to estimate correctly the proportion of air, I merely mention its presence, and allow 62.4 lbs., as in the case of your pump, for each cubic foot of discharge. This gives Messrs. Easton's pump a discharge of 140.77 tons of water per minute, or nearly 41 per cent. more than the makers have claimed for it, and as the lift was 7.0833 ft. instead of 6 ft., the work done was equal to 67.68 horse power, or 63.6 per cent. greater than the makers claim. I cannot quite believe that had the water been discharged into a gauge tank, the quantity actually thrown per minute would have weighed 140.77 tons; but with the wish not to under-estimate, for your guidance, the capabilities of a pump occupying the place of the rival to your own, I have, wherever any doubt has arisen as to the true mode of calculating the discharge, adopted that, giving to Messrs. Easton's pump the highest result.

The power exerted at the same time by Messrs. Easton's engines was ascertained. Diagrams, taken from both the top and bottom of both cylinders, are herewith annexed. The diagrams from the bottom of the cylinders are nearly worthless, however, on account of the length and comparatively small diameter of the pipe through which steam was carried from the bottom of the cylinder to the indicator, the latter being placed at the top of the cylinder, and quite 2½ ft. from the bottom.

The pressure at the top of the cylinder has been taken as the true pressure, the engine man having stated that the slide valves were carefully set to admit steam equally to the top and bottom of the cylinder. The mean effective pressure, therefore, at 52 revolutions, is 29·53 lbs. The indicator made by Messrs. Elliott Brothers, was, I was assured, and have reason to believe, frictionless, so that no deduction is to be made on account of indicator friction. There was no means of ascertaining the friction of the engines; but this must have been somewhat less, as measured in lbs. per square inch of piston, than in the case of your own engines. Messrs. Easton's engines had a stroke and connecting rods of good length, a parallel motion, instead of cross-head guide blocks; the connecting rod, instead of taking on to a crank, of the full diameter of the shaft, as in your engines, grasped a small crank pin; and in Messrs. Easton's engines there was a heavy geared wheel, serving as a fly-wheel, and having a counter weight. It may be, however, that the friction of the bevil gearing was enough to bring the whole friction between the piston and the pump up to that of your engines, and therefore I have estimated for both a pressure of 1½ lbs. as that required to run the engines *per se*, and an additional friction due to the load, as equal to one-seventh of the additional pressure on the pistons over and above 1½ per square inch. This gives a nett pressure of 24 lb. in Messrs. Easton's engines, and 94.44 horse power actually applied to drive the pump. The useful work done being equal to 67·68 horse power, this is 71⅔ per cent. of the power applied, as contrasted with 83.2 per cent. in the case of your pump. As compared with the full theoretical efficiency of 100 per cent., your pump reached 11½ per cent. nearer to this than Messrs. Easton's: and as compared directly with Messrs. Easton's pump, yours did 16 per cent. more work in proportion to the power applied.

Should the estimate of engine friction have been too high, the efficiency of both pumps would be correspondingly less than I have calculated, but your pump would still retain the same relative advantage. The results attained may be recapitulated as follows :—

MESSRS. GWYNNE & CO.'S PUMP.

Diameter of disc, 45".
Revolutions per minute, 200.
Lift, including friction of pipes, 20 ft. 8¾ in.
Water discharged per minute, 3·268 cubic feet.
Water discharged per minute, 91·03 tons.
Equivalent work done, 128·1 horse power.

Nett power applied, 154 horse power.
Useful effect attained, 83·18 per cent.
Velocity of periphery of pump, 41·886 ft. per second.
Height corresponding to this velocity, 27·207 ft.

Messrs. Easton, Amos, & Son's Pump.

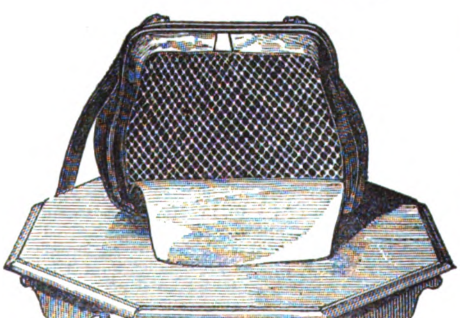
Diameter of disc, 4'5".
Revolutions per minute, 124.
Lift, including friction of pipes, 7 ft. 1 in.
Water discharged per minute, 5053·64 cubic feet.
Water discharged per minute, 140·77 tons.
Equivalent work done, 67·68 horse-power.
Nett power applied, 94·44 horse-power.
Useful effect attained, 71·66 per cent.
Velocity of periphery of pump, 28·675 ft. per second.
Height corresponding to this velocity, 12·725 ft.

I am, Gentlemen,
Your obedient servant,
Zerah Colburn.

SCHÄFER'S PATENT BULLION BAG.

Messrs. Schafer, of Golden-square, whose safety bag-lock we noticed in our pages a short time back, have recently patented a very important invention in bags for carrying papers, bullion, and other valuables. The invention consists in inserting a strong steel gauge or chain work, between the outer leather and the inner lining, so as to prevent the bag being cut, opened, or ripped by any sharp implement. The annexed engravings illustrate the invention fitted to travelling bags, the smaller figure shows a tourist bag, with a portion of the outer leather cut away, to expose the wire

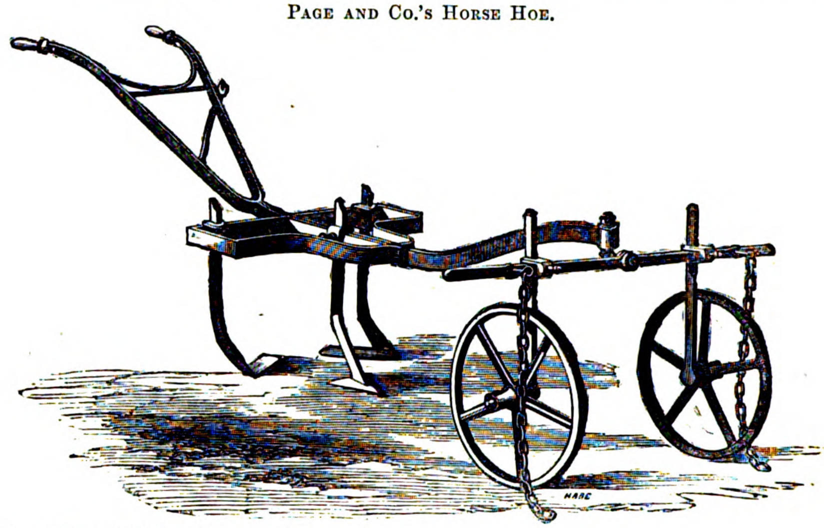
Schafer's Protected Bag.



Schafer's Protected Tourist's Bag.

gauze with which it is lined. The larger figure shows an ordinary travelling bag, fitted with chain work. We understand Messrs. Schäfers are making bags in the form of a sack, suitable for the use of the Post-office and bankers, having a chain-strap or band to fasten the same. It will be seen by the above description, that Messrs. Schäfers can supply the public with a bag which will withstand the curiosity of intruders, and afford security to its contents. We submit this invention to the consideration of merchants and others, having occasion to send valuable papers or articles by rail or other conveyance.

Page and Co.'s Horse Hoe.

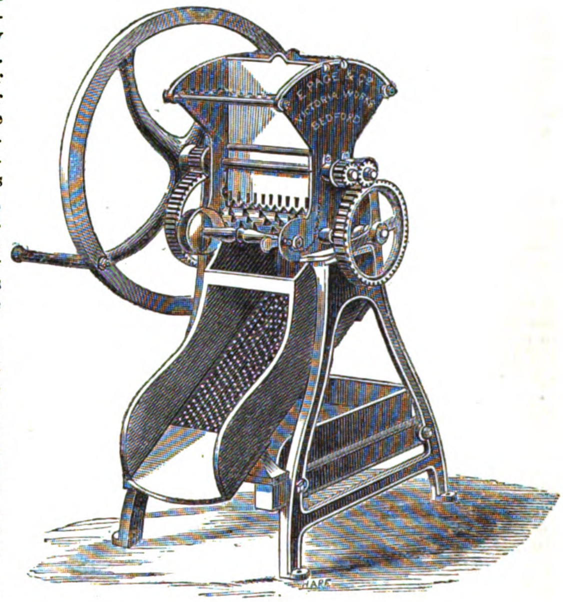


PAGE AND CO.'S OIL CAKE BREAKER AND HORSE HOE.

The annexed engravings show some implements that appeared at the Smithfield Club Show, and exhibited by Messrs. E. Page and Co., of Bedford. The horse hoe is for either ridge or flat, and can be converted into a four row wheat or barley hoe, taking the ridges at 9 inches apart. This implement is entirely of wrought-iron, except the wheels. A universal joint is fitted in the centre of the front bar, upon which the implement can swing. The centre hoe slides along the beam, and the side hoes can be placed farther apart. On hard ground, two grubbers may be placed on the front bars of the frame.

The oil-cake breaker is neatly arranged. The lids in the hopper can be made to fall on each side, so that a capacious box is formed to receive the broken cake when required to be twice ground. The rollers work inside a rack or comb, which prevents adhesion of cake when in a damp state. The rollers are kept parallel by a double eccentric working on each end of the roller. It will break seven different sizes. The whole is on an iron frame, having a screen and strainer for dust, and it can be worked by a boy.

Page and Co.'s Oil Cake Breaker.



INSTITUTION OF ENGINEERS IN SCOTLAND.

First Meeting of Session, 29th Oct., 1862.

Results of an Experimental Inquiry into the Comparative Tensile Strength and other Properties of various kinds of Wrought Iron and Steel.

By Mr. David Kirkaldy.

Mr. Kirkaldy exhibited several cases of the fractured specimens upon which his experiments were made; and, by way of introduction to the discussion, there were read from his Treatise the following conclusions arrived at by Mr. Kirkaldy in the course of his inquiry :—

1. The breaking strain does *not* indicate the quality, as hitherto assumed.

2. A *high* breaking strain may be due to the iron being of superior quality, dense, fine, and moderately soft, or simply to its being very hard and unyielding.

3. A *low* breaking strain may be due to looseness and coarseness in the texture, or to extreme softness, although accompanied by very close and fine quality.

4. The contraction of area at fracture, previously overlooked, forms an essential element in estimating the quality of specimens.

5. The respective merits of various specimens can be correctly ascertained by comparing the breaking strain *jointly* with the contraction of area.

6. Inferior qualities show a much greater *variation* in the breaking strain than superior.

7. Greater differences exist between small and large bars in coarse than in fine varieties.

8. The prevailing opinion of a rough bar being stronger than a turned one is erroneous.

9. Rolled bars are slightly hardened by being forged down.

10. The breaking strain and contraction of area of iron plates are greater in the direction in which they are rolled than in a transverse direction.

11. A very slight difference exists between specimens from the centre and specimens from the outside of crank-shafts.

12. The breaking strain and contraction of area are greater in those specimens cut lengthways out of crank-shafts than in those cut crossways.

13. The breaking strain of steel, when taken alone, gives no clue to the real qualities of various kinds of that metal.

14. The contraction of area at fracture of specimens of steel must be ascertained as well as those of iron.

15. The breaking strain, *jointly* with the contraction of area, affords the means of comparing the peculiarities in various lots of specimens.

16. Some descriptions of steel are found to be very hard, and, consequently, suitable for some purposes; whilst others are extremely soft, and equally suitable for other uses.

17. The breaking strain and contraction of area of *puddled*-steel plates, as in iron plates, are greater in the direction in which they are rolled; whereas in *cast*-steel they are less.

18. Iron, when fractured suddenly, presents in-

variably a crystalline appearance; when fractured slowly, its appearance is invariably fibrous.

19. The appearance may be changed from fibrous to crystalline by merely altering the shape of the specimen so as to render it more liable to snap.

20. The appearance may be changed by varying the treatment so as to render the iron harder and more liable to snap.

21. The appearance may be changed by applying the strain so suddenly as to render the specimen more liable to snap, from having less time to stretch.

22. Iron is less liable to snap the more it is worked and rolled.

23. The "skin" or outer part of the iron is somewhat harder than the inner part, as shown by appearance of fracture in rough and turned bars.

24. The mixed character of the scrap-iron used in large forgings is proved by the singularly varied appearance of the fractures of specimens cut out of crank-shafts.

25. The texture of various kinds of wrought-iron is beautifully developed by immersion in dilute hydrochloric acid, which, acting on the surrounding impurities, exposes the metallic portion alone for examination.

26. In the fibrous fractures the threads are drawn out, and are viewed externally, whilst in the crystalline fractures the threads are snapped across in clusters, and are viewed internally or sectionally. In the latter cases the fracture of the specimen is always at right angles to the length; in the former it is more or less irregular.

27. Steel invariably presents, when fractured slowly, a silky fibrous appearance; when fractured suddenly, the appearance is invariably granular, in which case also the fracture is always at right angles to the length; when the fracture is fibrous, the angle diverges, always more or less from 90 deg.

28. The granular appearance presented by steel suddenly fractured is nearly free of lustre, and unlike the brilliant crystalline appearance of iron suddenly fractured; the two combined in the same specimen are shown in iron bolts partly converted into steel.

29. Steel which previously broke with a silky fibrous appearance is changed into granular by being hardened.

30. The little additional time required in testing those specimens, whose rate of elongation was noted, had no injurious effect in lessening the amount of breaking strain, as imagined by some.

31. The rate of elongation varies, not only extremely in different qualities, but also to a considerable extent in specimens of the same brand.

32. The specimens were generally found to stretch equally throughout their length until close upon rupture, when they, more or less, suddenly drew out, usually at one part only, sometimes at two, and, in a few exceptional cases, at three different places.

33. The ratio of ultimate elongation may be greater in short than in long bars in some description of iron, whilst in others the ratio is not effected by difference in the length.

34. The lateral dimensions of specimens form an important element in comparing either the rate of, or the ultimate, elongations—a circumstance which has been hitherto overlooked.

35. Steel is reduced in strength by being hardened in water, while the strength is vastly increased by its being hardened in oil.

36. The more highly steel is heated (without, of course, running the risk of being burned) the greater is the increase of strength, on its being plunged into oil.

37. In a highly converted or hard steel, the increase in strength and in hardness is greater than in a less converted or soft steel.

38. Heated steel, by being plunged into oil, instead of water, is not only considerably *hardened*, but *toughened* by the treatment.

39. Steel plates, hardened in oil, and joined together with rivets, are fully equal in strength to an unjointed soft plate, or the loss of strength by rivetting is more than counterbalanced by the increase in strength by hardening in oil.

40. Steel rivets, fully larger in diameter than those used in rivetting iron plates of the same thickness, being found to be greatly too small for rivetting steel plates, the probability is suggested that the proper proportion for iron rivets is not, as generally assumed, a diameter equal to the thickness of the two plates to be joined.

41. The shearing strain of steel rivets is found to be about a fourth less than the tensile strain.

42. Iron bolts, case-hardened, bore a less breaking strain than when wholly iron, owing to the superior tenacity of the small proportion of steel being more than counterbalanced by the greater ductility of the remaining portion of iron.

43. Iron highly heated, and suddenly cooled in water, is hardened, and the breaking strain, when gradually applied, increased, but, at the same time, it is rendered more liable to snap.

44. Iron, like steel, is softened, and the breaking strain reduced, by being heated and allowed to cool slowly.

45. Iron, subjected to the cold-rolling process, has its breaking strain greatly increased by being made extremely hard, and not by being "consolidated," as previously supposed.

46. Specimens cut out of a crank ft are improved by additional hammering.

47. The galvanizing, or tinning, of iron plates, produces no sensible effects on plates of the thickness experimented on. The results, however, may be different should the plates be extremely thin.

48. The breaking strain is materially effected by the shape of the specimen. Thus the amount borne was much less when the diameter was uniform for some inches of the length than when confined to a small portion—a peculiarity previously unascertained, and not even suspected.

49. It is necessary to know correctly the exact conditions under which any tests are made, before we can equitably compare results obtained from different quarters.

50. The startling discrepancy between experiments made at the Royal Arsenal, and by the writer, is due to the difference in the shape of the respectiv specimens, and not in the difference in the two testing machines.

51. In screwed bolts, the breaking strain is found to be greater when old dies are used in their formation than when the dies are new, owing to the iron becoming harder by the greater pressure required in forming the screw thread when the dies are old and blunt, than when new and sharp.

52. The strength of screw-bolts is found to be in proportion to their relative areas, there being only a slight difference in favour of the smaller, compared with the larger, sizes, instead of the very material difference previously imagined.

53. Screwed bolts are not necessarily injured, although strained nearly to their breaking point.

54. A greet variation consists in the strength of iron bars which have been cut and welded; whilst some bear almost as much as the uncut bar, the strength of others is reduced fully a third.

55. The welding of steel bars, owing to their being so easily burned by slightly overheating, is a difficult and uncertain operation.

56. Iron is injured by being brought to a white or welding heat, if not at the same time hammered or rolled.

57. The breaking strain is considerably less when the strain is applied suddenly, instead of gradually, though some have imagined that the reverse is the case.

58. The contraction of area is also less when the strain is suddenly applied.

59. The breaking strain is reduced when the iron is frozen; with the strain gradually applied, the difference between a frozen and unfrozen bolt is lessened, as the iron is warmed by the drawing out of the specimen.

60. The amount of heat developed is considerable when the specimen is suddenly stretched, as shown in the formation of vapour from the melting of the layer of ice in one of the specimens, and also by the surface of others assuming tints of various shades of blue and orange, not only in steel, but also, although in a less marked degree, in iron.

61. The specific gravity is found generally to indicate pretty correctly the quality of specimens.

62. The density of iron is *decreased* by the process of wire-drawing, and by the similar process of cold-rolling, instead of *increased*, as previously imagined.

63. The density in some descriptions of iron is also decreased by additional hot-rolling in the ordinary way; in others, the density is very slightly increased.

64. The density of iron is decreased by being drawn out under a tensile strain, instead of increased, as believed by some.

65. The most highly converted steel does not, as some may suppose, possess the greatest density.

66. In cast-steel the density is much greater than in puddled steel, which is even less than in some of the superior descriptions of wrought-iron.

The breaking strain per square inch of wrought-iron is generally stated to be about 25 tons for bars and 20 tons for plates. This corresponds very nearly with the results of the writer's experiments, of which the following table presents a condensed summary:—

	Lbs. Highest.	Lbs. Lowest.	Lbs. Mean.	Tons.
188 Bars, rolled,	68,818	44,584	57,555	— 25¾
72 Angle-iron, &c.,	63,715	37,909	54,729	— 24½
167 Plates, lengthways	62,544	37,474	50,737	— 21¾
160 Plates, crossways,	60,756	32,450	46,171	

Although the *breaking* strain is generally assumed to be about 25 tons for bars and 20 tons for plates, very great difference of opinion exists as to the amount of *working* strain, or the load which can with safety be applied in actual practice. The latter is variously stated at from a third to a tenth. It will be observed that whilst much discussion has arisen as to the amount of working strain, or the ratio the load should bear to the breaking strain, the important circumstance of the *quality* of the iron, as influencing the working strain, or the ratio the load should bear to the breaking strain, the important circumstance of the *quality* of the iron, as influencing the working strain, has been overlooked. The Board of Trade limits the strain to five tons, or 11,200 lbs. per square inch.

It must be abundantly evident, from the facts which have been produced, that the breaking strain, when taken alone, gives a false impression of, instead of indicating, the real quality of the iron, as the experiments which have been instituted reveal the somewhat startling fact, that frequently the inferior kinds of iron actually yield a higher result than the superior. The reason of this difference was shown to be due to the fact, that whilst the one quality retained its original area, only very slightly decreased by the strain, the other was reduced to less than one-half. Now, surely this variation, hitherto unaccountably completely overlooked, is of importance, as indicating the relative hardness or softness of the material, and thus, it is submitted, forms an essential element in considering the safe load that can be practically applied in various structures. It must be borne in mind that although the softness of the material has the effect of lessening the amount of the *breaking* strain, it has the very opposite effect as regards the *working* strain. This holds good for two reasons: first, the softer the iron the less liable it is to snap; and, second, fine or soft iron, being more uniform in quality, can be more depended upon in practice. Hence the load which this description of iron can suspend with safety may approach much more nearly the limit of its breaking strain than can be attempted with the harder or coarser sorts, where a great margin must necessarily be left.

Special attention is now solicited to the practical use that may be made of the new mode of comparison introduced by the writer, viz.: *the breaking strain per squrre inch of the* FRACTURED *area of the specimen, instead of the breaking strain per square inch of the* ORIGINAL *area.*

As a necessary corollary to what he has just endeavoured to establish, the writer now submits, in addition, that the *working* strain should be in proportion to the breaking strain per square inch of fractured area, and not to the breaking strain per square inch of original area, as heretofore. He does not presume to say what that ratio should be, but he fully maintains that some kinds of iron experimented on by him will sustain with safety more than double the load that others can suspend, especially in circumstances where the load is unsteady, and the structure exposed to concussions, as in a ship, or to vibratory action, as in a railway bridge.

The writer has not attempted to explain the cause of the mysterious change produced on steel by heating it and plunging it into water, or the no less singular result effected by plunging it, when heated, into oil. Neither has he tried to account for the mysterious change produced by subjecting iron to the processes of cold-rolling or wire-drawing. The explanation offered by some, of this difficult question, that the iron or steel are *condensed* by the processes to which they are subjected, is completely contradicted by fact, the metal being actually *expanded*. The aim of the writer being strictly to ascertain facts, and state the conclusions which he considers to be fairly deducible from them, he has not felt himself warranted in attempting to speculate on a subject respecting which so little is yet known.

In conclusion, the writer ventures only to express a hope that the experiments, on which he has been so long and unremittingly engaged, may not prove wholly unserviceable to practical science and the world at large. The importance of possessing a thorough knowledge of the capabilities and strength of substances on which the lives and property of so many human beings depend, no one will attempt

to deny. The only excuse, if, indeed, excuse it can be called, for employing an inferior description of material in the rearing of structures on the stability of which such momentous issues are involved, is ignorance or misapprehension of its proper quality. The writer has endeavoured, by a plain statement of facts, to furnish some information on a subject which seems, until now, to have been denied the attention which its paramount importance demands. Were this question fairly taken up and considered, some security might be afforded against the repetition, in future, of disasters occasioned by its being so often practically ignored. The necessity of using nothing but the very best description of metal, where human life or valuable property is at stake, may, he trusts, come soon to be more generally recognized than it is at present. And an increased demand for the finer varieties may conduce to a generous emulation amongst the manufacturers to improve still further the quality of their productions. Should his labours tend in any way, even the smallest degree, to diminish the annual sacrifice of life and property occasioned by faulty material and workmanship, he will feel the satisfaction that they have, at least, not been entirely in vain.

Mr. Kirkaldy exhibited 490 selected specimens, which were contained in five cases, namely:—

In Case I. 9 iron bars, showing elongation and lateral contraction.
1 iron plate, ditto.
1 steel plate, ditto.

In Case II. 42 steel bars, showing fractures and contraction of area.
105 iron bars, ditto.

In Case III. 36 steel plates, ditto.
60 iron plates, ditto.
24 angle-iron, &c., ditto.

In Class IV. 36 iron bars, showing fractures and effects of difference of shape.
40 iron bars, showing fractures and effects of difference of treatment.
12 steel bars, ditto.
10 iron plates, ditto.
15 iron bars, showing fractures and effects of strains suddenly and gradually applied.

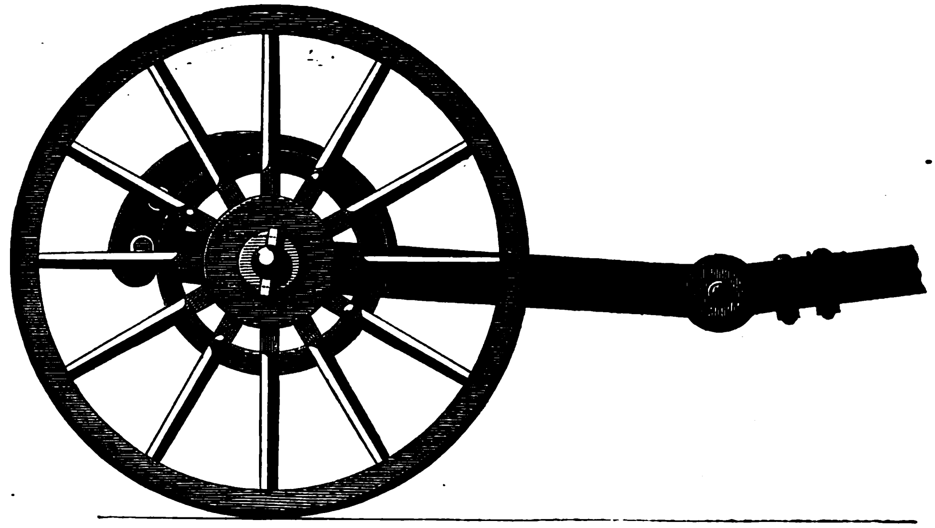
In Case V. 46 iron bars, showing fractures of screwed bolts.
12 iron bars, showing fractures of welded joints.
2 steel bars, ditto.
26 iron bars, showing texture as developed by acid.
8 iron plates, ditto.
1 iron plate, with surface cold-rolled.
4 iron bars, with surface cold-rolled.

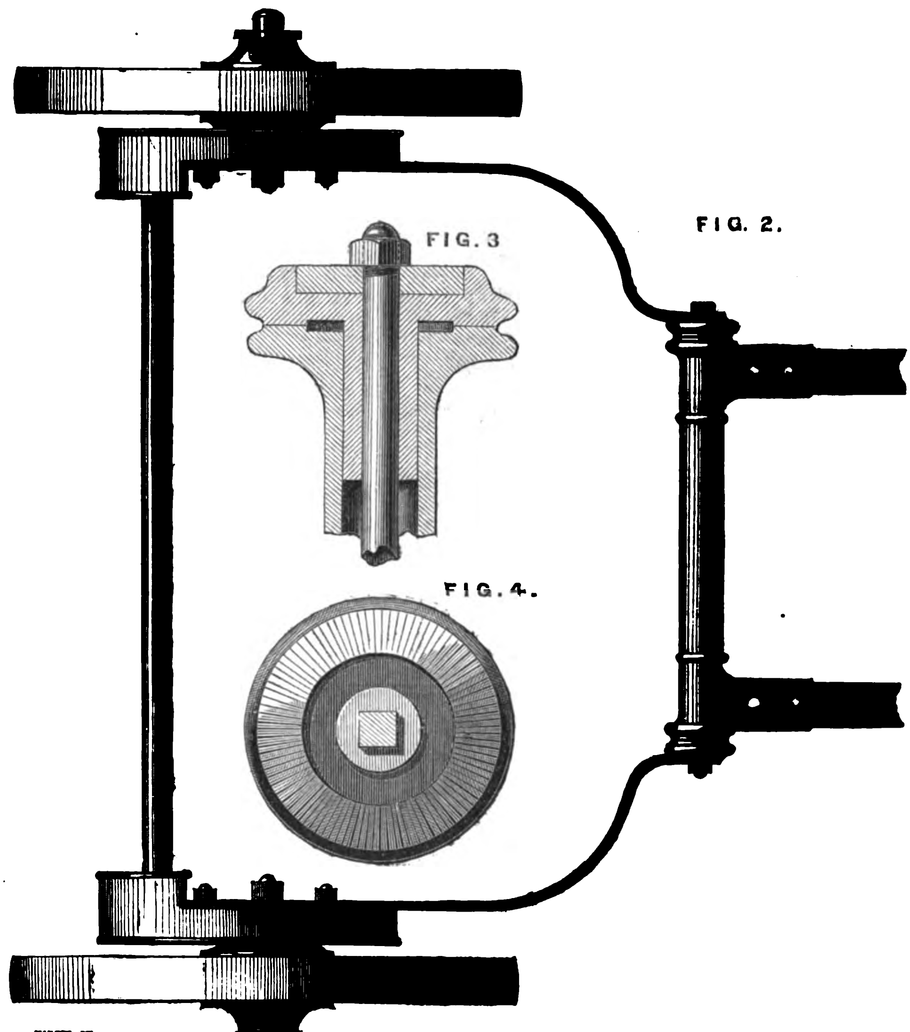
The discussion that ensued on the above will be given next week.

BOBY'S HAYMAKER.

BOBY'S HAYMAKER.

Fig 1.





The accompanying cuts illustrate the new haymaking machine of Mr. Boby. The several parts of this implement are so arranged that they will operate in either direction. To this end the tines are made straight, instead of curved, as usual, so that in whichever direction the rotating frame may be driven, the teeth will act on the hay. The reverse action of the rotating frame is obtained by means of double pinions, which are capable of sliding along their shaft, so that they may be put in gear with the driving cog wheel affixed to the spokes of the travelling wheels of the machine when required. The tines of the implement may be supported in a raised position, nearer to or further from the ground, by the aid of a disc adjustment, which is adapted to the front bar of the machine. The shafts are adapted to a hollow front bar which carries part of the disc adjustment, and they are, therefore, capable of being turned upon a central point, which will admit of the travelling wheels being lifted off the ground, so that they may be taken off their axles without inconvenience. The fork heads that carry the teeth project beyond the circumference of the running wheels, and, therefore, when the fork heads are lowered, they will form a fulcrum on which the machine will rest, when the wheels are to be lifted off the ground.

In the engravings, Fig. 2 represents a plan of the principal parts of this haymaking machine. Fig. 1 is a side elevation of the same; the travelling wheels turn upon stud axles fixed to the side frames of the machine, and the axle of the revolving fork-head cylinder rotates in bearings secured on the ends of the side arms, in the usual manner. If it be desired to cause the cylinder to rotate in either direction, the tines must be made straight, as before mentioned, instead of curved, as is usually the case. As the straight tines are secured to the rotating fork cylinder in the usual manner, this attachment is not shown. The front hollow shaft bar, to which the shafts are secured, carries at each end the discs. A straight rod, seen best in the detached Figs. 3 and 4, passes through the hollow front shaft, and also through the discs, which are secured to the wrought-iron side bars of the framing. The rod is provided at one end with a head, and is screwed at the other end, and carries a nut; so that, by turning or screwing up the nut, the surfaces of the discs may be brought into close contact, and thereby form a friction clutch,

BUNNETT'S PATENT REVOLVING SHUTTERS.

FIG. 1.

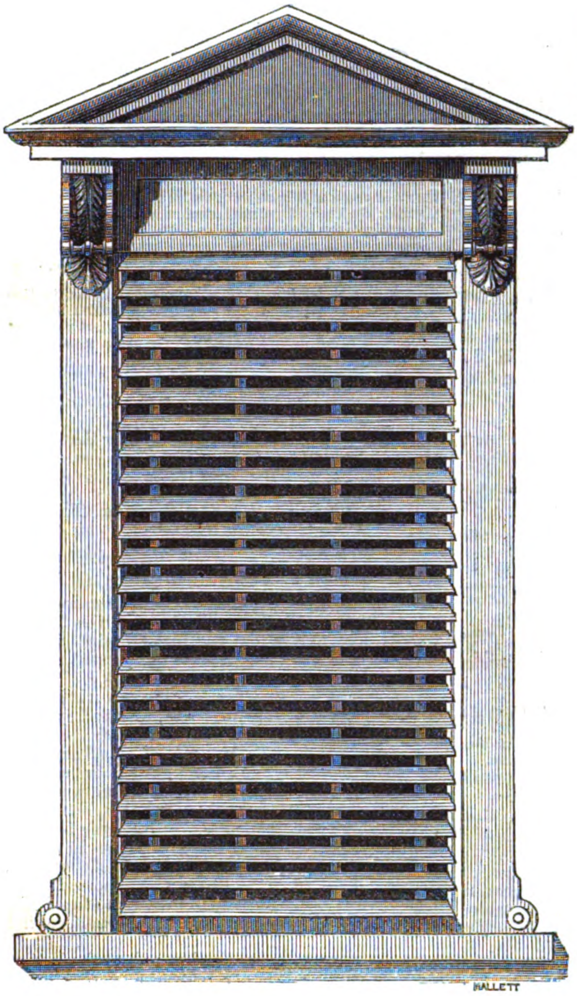


FIG. 2.

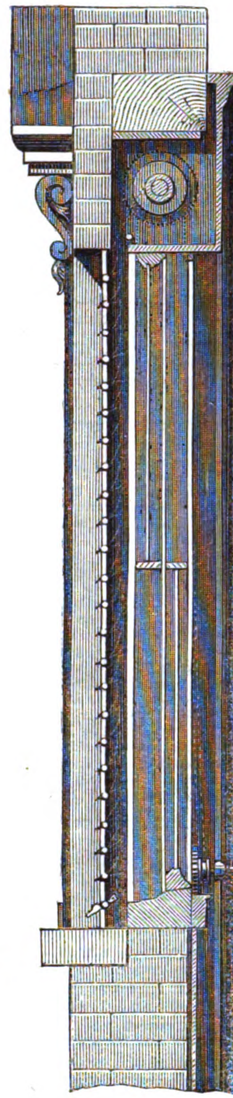

FIG. 3.

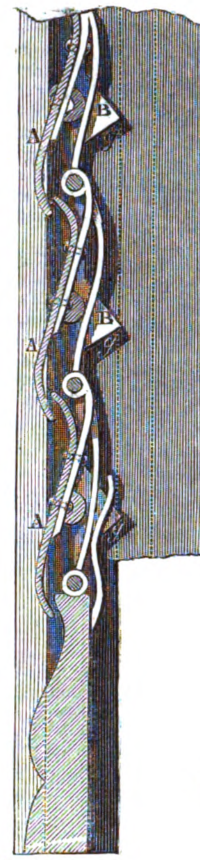

FIG. 4.

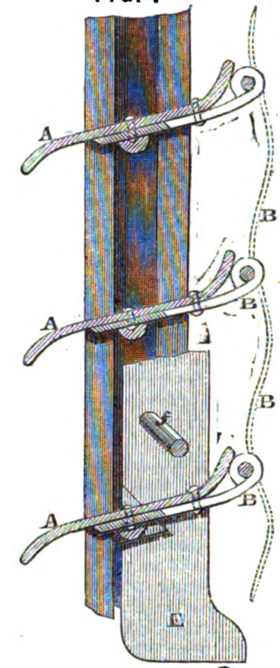

FIG. 5.

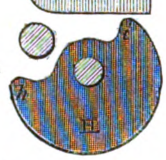

FIG. 6.

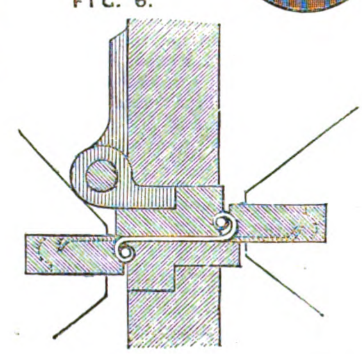

which will hold the parts together in any desired position. It will thus be understood that side frames and shafts may be turned upon the axis of the rod as a centre of motion, when the nut is loosened. The relative position of these parts will be thereby changed, and they may be secured in their new position by simply screwing up the discs tightly together.

BUNNETT'S PATENT REVOLVING SHUTTERS.

A VARIETY of improvements have taken place during the last few years in window shutters, and one of the inventions, which we illustrate this week, is an improved shutter, recently patented by Mr. J. Bunnett, of Deptford. The invention consists in so shaping and connecting the plates or louvre boards as to enable them to be placed at any angle, similar to venetian blinds, to admit light into any building to which they may be placed. For this purpose each lath is mounted on a central axis, which moves up and down in the guiding shutter grooves; the upper edges of the laths are connected together by hinged flaps. A portion of the inner side of each shutter groove turns on pivots, and when it is desired to use the shutter as a venetian blind, this limb of the groove is turned a quarter round, when the laths are free to turn on their axes, and may be set at any required inclination.

Fig. 1 of the accompanying engravings is a front elevation of a shutter so constructed. Fig. 2, a side section of the same; Figs. 3 and 4 are sectional views on a larger scale; one showing the plates open, the other showing them closed.

A, A, are the laths, each of which has a projecting central axis at each end; B, B are flat hinges, jointed at their upper ends to the shutter roller, and also to the upper parts of each of the laths. The axes of the laths slide up and down in grooves at the sides of the window. Attached to the lower end of a moveable limb there is an inclined rising step or quadrant, upon which the foot of the vertical bar E rests, its fore edge laying flush with the back of the groove. When the shutter is to be used as a venetian blind, it is lowered, and the limb turned round a quarter of a revolution, when the bar E will be lifted by the rising step, and, by means of guide pins working in the inclined slots *f*, the bar will be thrown forward, when the notches *g*, in the front edge of the bar, come in contact with and form bearings for the axes of the laths, which may then be set at any required angle by means of a handle attached to the lower bar or rail of the shutter. When the shutter is to be closed, the limb is turned back into its original position; the bar E then falls back into its place, flush with the back face of the groove. Fig. 5 shows another mode of actuating the bar E; in lieu of the rising step before described, a cam H is placed at the lower part of the groove. When the shutter is lowered, the axes of the lowermost lath *a* comes down upon and by its weight depresses the point *h* of the cam, which causes the opposite point *i* to rise and lift the bar E upward and forward; the lathes may then be opened as required. On beginning to wind up the shutter, the cam H and the bar E fall back into their original positions. The curvature and shape of the plates or louvre boards are effected by suitable machinery, so that both edges of the laths are bent simultaneously. Fig 6 shows the action of the dies. The dotted lines show the form of the lath after the first preliminary bending, in which state it is fed into the finishing part of the machine. In this figure it will be seen that the upper die is hinged to the hold down, for the purpose of enabling it to leave the finished lath without injury. As the revolution of the cranks causes the die blocks to recede, the finished lath falls out. By regulating the distances of the dies, any required amount of curvature may be given to the edges of the lath from a portion to the whole of a circle.

Orders have been received for the construction of another target at Shoeburyness, much larger and stronger than any one that has been experimented upon. It is to be constructed of plates varying from 5½ to 6½ and 7 in. thick. The object of the target, and the experiments upon it, is to discover the maximum thickness of armour plates which cannot be penetrated with Armstrong or Whitworth guns as at present constructed.

NEW WATER GAUGE FOR STEAM BOILERS.

At a recent meeting of the North of England Institute of Mining Engineers—Nicholas Wood, Esq., president, in the chair—a discussion took place upon a paper read by Mr. S. C. Crone, of Killingworth, on Steam Boiler Explosions. In the course of the debate, in reply to the President, Mr. T. Y. Hall mentioned a plan that he had had in use in 1857, and described it to the meeting. His attention had been called to the matter by the conflicting evidence in the celebrated trial in Wales, viz., the Queen *v.* the Dowlais Iron Company, more commonly known as "the battle of the boiler gauges." In an ordinary boiler, he caused a narrow aperture to be made at the end, extending about 5 in. above and below the ordinary level of the water inside. In front of this aperture he placed a strong metal box, into which he fitted a piece of plate glass, and protected it by talc, so that the engineman could see the height of water at any time with perfect safety, and without any risk of failure, such as often happened with cocks, floats, and tubes. He adapted it so that glass could also be fitted in the sides of the projection, and, by placing a light on one side, the water could be seen at all hours of the night. A revolving valve was so placed as to be turned half-way round, to cut off the water and steam whenever it was necessary to clean the glass, or for any other purpose. This plan was applied to a boiler on the premises of Mr. H. Watson, High Bridge Foundry, Newcastle, in 1857, and found to answer admirably. It was also tested without the aperture, cocks and taps alone forming the channel of communication with the water inside the boiler and the talc-protected chamber. He (Mr. Hall) obtained provisional protection for his plan in 1857, but did not persevere with the patent, although he considered that the plan was preferable to any other in existence; and he remained of the same opinion.—The President: Would not the aperture weaken the boiler?—Mr. Hall replied in the negative. The apparatus, being screwed on to the boiler, actually strengthened instead of weakening it (?) The boiler end, instead of having an aperture of ½ in. by 10 in., might be perforated with holes of ½ in. diameter, 1 in. apart, which would answer the same purpose, and would be still stronger. In his experiments he had the glass intentionally cracked, but the talc lining still prevented the escape of steam and water, and showed the height of the latter with great distinctness. A Mr. Chandler, of Mark-lane, London, had recently patented a somewhat similar invention; but in Mr. Chandler's plan there was no protection to the glass, and it necessitated the use of two cocks. When it was required, his (Mr. Hall's) apparatus could be extended through brickwork any distance from the boiler, so as to do away with floats, cocks, and the small round tubes, and enable the engineman to see the state of the water-level in the boiler, without any such intervention as has heretofore been applied. A float, made of cork, india rubber, or some other elastic substance, might be put in at the top of the apparatus by a small rod, but he did not consider it necessary. It might, however, be used at any time as a rubber, to take the steam off the inside of the talc.

PATENTS.

The Birmingham Chamber of Commerce has lately received a communication from the Patent Law Commissioners, containing the following questions:—1. Should the cost of obtaining letters patent be diminished or increased; if either, to what extent; and should the payments be made in one sum, or by annual or other instalments? 2. Does the present mode of obtaining patents appear to you satisfactory? Is it your opinion that there ought to be a preliminary investigation of a more searching character than that which at present takes place? If so, how should the tribunal be constituted before which such investigation shall be conducted, and should the judgment of such tribunal be final? 3. Should the investigation be *ex parte* or public, and subject to opposition? Should the present practice as to caveats be adhered to? 4. Do you consider that patents ought to be refused on the ground of the trifling and frivolous nature of the inventions for which they are claimed? 5. Should greater facilities be provided for the repeal of invalid patents? 6. Do you consider that any change should be made in the tribunal appointed to try actions and suits instituted by patentees? 7. Should the granting of licenses, in your opinion, be made compulsory, and can you suggest any practicable method by which this should be done? 8. Have you any reason to suppose that public inconvenience is caused by the multiplicity of patents? 9. Do you think it expedient that patents should be granted to foreigners residing abroad, or to their nominees? 10. Is it expedient to make any, and if so, what alterations in the law relating to prolongations and confirmations? 11. Is it expedient to make any, and if so, what alterations in the law respecting disclaimers and memoranda of alterations?

Meetings for the Week.

Mon.—*London Inst.*, "On the House of Commons, Horace Walpole, and Modern Satire," by Shirley Brooks, Esq., at 7 p.m.

Tues.—*Royal Inst.*, "On Air and Water" (juvenile lecture), by Professor Frankland, at 3 p.m.

Wed.—*Geological Soc.*, 1, "On the Lower Carboniferous Brachiopoda of Nova Scotia," by T. Davidson, Esq. 2, "On the Gravel Deposits of Ludlow, Hereford, and Skipton," by T. Curley, Esq. 3, "On the Northerly Extension of the Upper Silurian Passage Beds to Lincley Salop," by G. E. Roberts, Esq. 4, "On some Crustacean Tracks from the Old Red Sandstone near Ludlow," by G. E. Roberts, Esq., at 8 p.m.

Thur.—*Royal Inst.*, "On Air and Water" (juvenile lecture), by Professor Frankland, at 3 p.m.

Fri. — *London Inst.*, "On the Chemistry of the Non-Metalic Elements," by F. Field, Esq., at 7 p.m.

Sat. — *Royal Inst.*, "On Air and Water" (juvenile lecture), by Professor Frankland, at 3 p.m.

Legal Intelligence.

Court of Common Pleas, Dec. 17.—Spencer *v.* Jack and Rollo.—Mr. Lush, Q.C., Mr. Streeton, and Mr. T. Webster, appeared for the plaintiff; Mr. Bovill, Q.C., Mr. Hindmarch, Q.C., and Mr. T. Jones, for the defendants. This case, which had occupied the court for three days, was brought to a conclusion. It was an action brought on behalf of a consulting engineer, of Newcastle-upon-Tyne, against the defendants, engine makers, of Liverpool, for the infringement of a patent taken out by the plaintiff in 1860 for certain improvements in marine steam engines. The claim of the plaintiff under his patent was twofold:—First, in the arrangement of inverted direct-acting screw engines, a disposition of surface condensers, by which the external casing thereof forms part of the main framing, and is placed between and under the cylinders of such engines, and the tubes whereof, being horizontal or slightly inclined, are placed across the line of the keel or propeller shaft; secondly, in the arrangement of paddle-wheel engines, a disposition of surface condensers, by which the external casing thereof is placed between the cylinders, and may or may not form part of the main framing of such engine. The tubes whereof of such condensers, being horizontal or slightly inclined, are placed across the line of paddle-shaft and in line with the keel. The defendants denied the novelty of the invention; but, after a short deliberation, the jury found for the plaintiff as regarded both claims.

The Government steam-ram, "Hector," built by R. Napier and Sons, Govan, is berthed in the Victoria Harbour, Greenock, where she is to receive her machinery and boilers, and otherwise fitted for sea. Her draught of water is now about 21 ft. The dimensions of the "Hector" are 286 ft. long, 56 ft. broad, and 38 ft. deep, her tonnage being 4,063. She will be propelled by a pair of horizontal engines of 800-horse power, prepared by the builders, and fitted with a screw. Her masts and bowsprit will be iron, and the latter will be constructed so as to double up when necessary. The cost of her hull alone will be over £170,000. The "Hector" will carry twenty-four 68-pounders, and six 110-pounders on the main-deck, with a 110-pounder pivot-gun on the upper deck at the stem and stern. Her iron-plating, of 4½ in. thick, will extend to a depth of 5 ft. below the water line.

TO CORRESPONDENTS.

Received.—W. A., J. D. and Sons, J. H., John Goucher (next week), J. C. and Co., J. W., W. R.

J. Garland (Ashton-under-Lyne).—Thanks. Of course the area of a piston cannot be increased by corrugating its surface. *Heating* surface can be increased in this way. The patent you refer to is a scientific absurdity. A shilling book on mechanics would have saved the patentee his £30.

Tyro—The formula you require is $(1-e)\,Vg$, wherein e is specific weight of the body, V the volume of the body immersed, and g the known pressure of the water for any given depth. Of course the total lift is taken as acting on the centre of gravity.

Iron.—As you will have seen, we published your letter last week. We know at present of no work or really *scientific* investigations into the subject. You will see by the accounts of the trials in our paper that it is not a *purely* mechanical question. Other forces come into play.

No notice can be taken of anonymous communications. Whatever is intended for insertion must be authenticated by the name and address of the writer; not necessarily for publication, but as a guarantee of his good faith.

Correspondence.

WHEEL TRAFFIC THROUGH THE THAMES TUNNEL.

[We insert the following as a curiosity.]

TO THE EDITOR OF THE "MECHANICS' MAGAZINE."

Sir,—Having submitted to the Directors a plan for conveying wheel traffic through the Thames Tunnel, I thought a few particulars might interest some of your readers. Within the present shafts I propose to construct—

1, A cylindrical iron frame-work the whole depth of the shaft, formed, at intervals, of small cylinders to hold wooden sleepers.

2, Attached to the inner side of this frame-work are three lines of spiral railway, one above another.

3, Also, within the cylindrical frame-work, two circular platforms, of nearly equal area, one resting on the other—the upper platform to carry the load, viz., waggons, horses, &c.; this is free to subside or rise, but cannot revolve, being held by guide-frames. The lower platform is supported on 18 wheels, in tiers, to correspond with the three lines of rail. This lower platform has a cruciform hole in the centre.

As the rails coil round and round to the bottom, the weight on the upper platform bearing on the lower, both will descend till they reach the bottom, where a doorway is provided for the exit of the carriages.

4, In the centre of the iron cylinder is a vertical spindle, turning on a point at the bottom of the shaft. It is of cruciform shape, formed of timbers, to give it rigidity, and it passes through a corresponding hole, as before-mentioned, in the lower platform.

5, Over each shaft is an hydraulic engine, with three cylinders, working into a vertical shaft, and this is connected with the before-mentioned spindle by a peculiar clutch. It will be seen that the hydraulic engine gives motion to the vertical spindle, which conveys that motion to the lower platform by passing through the hole in the centre. By this means, without a single cog-wheel, it is in gear with the engine at all altitudes.

6, Means of storing up the surplus labour performed by the descending load.

If the motion of the engine can raise the platform, the latter, in descending, could move the engine by a suitable arrangement of the valves, provided the pressure on the pistons be low enough. I therefore propose *two* auxiliary accumulators, of different pressures. If the steam engine that supplies the great accumulator draws the water from the two auxiliaries, the labour of forcing will only equal the difference of pressure—thus, the labour will be economized.

I am, &c.,
George White.

Clarkson's Endowed School, Mansfield, Notts,
December 2, 1862.

THE PERSIAN GULF CABLE.

Sir,—Will you permit me to make a few observations respecting the general construction of the Persian Gulf cable now in process of manufacture. I think the particulars of important lines of cable cannot be made too public, in order, by degrees, to familiarize all who are concerned in such matters with every important item concerning them, espe-

cially of their construction, since such information will eventually enable them to compare, and judge, and form opinions more or less approximatively to correctness in proportion as they bring to bear upon the subject, and their reasoning and discerning faculties divested of indifference, pre-conceived notions, and untenable prejudices.

First, then, the cable in question has a conductor of one solid copper wire, 1-10th of an inch in diameter. Now, it is for us to examine the wisdom of this choice of conductor, which certainly savours of retrogression rather than advancement. This was the style of conductor first adopted in submarine and subterranean cables, but was subsequently abandoned, because if by any accident it should become broken, as was not unfrequently the case, the cable was rendered useless, since continuity was interrupted, and there was no help for it but to haul up the cable in order to make the necessary join: hence a strand of 7 wires, whose total diameters should equal the area of one large solid conductor, was invariably adopted as far preferable to the latter, since, if a break occur, which is seldom the case, it would only be of *one* wire, leaving the other six intact and perfect, and so not interfering with the continuity; but even this contingency is rendered extremely improbable by the recent improvements in making stranded copper wire joints. The result of this discovery was the universal adoption of stranded conductors, and it was and is generally considered an important step in advance of the original style; so much so, indeed, that the Government Committee thought proper to strongly recommend stranded conductors as the most efficient according to their notions of what a good conductor should be. There was only one objection that could be urged against them—an objection more fanciful than real, viz.: the interstices that would exist, and which it was supposed that no method of insulation, of whatever material, would perfectly fill up. But it is manifest, that if gutta-percha be the insulator, that the very fact of its being put in by a die process, and in a pulpy state, is quite sufficient to effectually prevent the existence of any interstice that could act prejudicially by the admission of water and air. And although india-rubber must be applied by a different method, it is equally clear to those practically acquainted with the matter, that this objection has no foundation, in fact; and if it had, the means of preventing it by the application of caoutchouc thread are perfect. Of course, a conductor of one solid wire is most likely to give way at the joints; these places in a single wire being necessarily weaker than any other point, or if not weaker, certainly not capable of bearing so much strain, because the nature of the join is such as to render the metal harsh and brittle, and thus even a bend at too acute an angle might cause the conductor to sever at the joint.

It may be urged that no strain should fall upon the conductor; but this belongs to the order of things which ought not to be. We are dealing with things as they are. It is notorious that strain does fall upon the conductor, and ever will so long as we adhere to ponderous cables of spiral iron wire, for these cables are necessarily of such immense weight as to elongate considerably when suspended to any great stretch in submersion; hence, the core being the only longitudinal portion of the cable, is the only portion that is called upon to bear the accumulated mass of its lumbering protector; and when you consider for a moment the breaking strain of any given size of copper wire, it is not difficult to divine the consequences. From whatever point of view this matter is observed, it must appear evident that stranded conductors are the more perfect, efficient, and, in every sense of the word, suitable for submarine cables, and that the departure from, or setting at nought of, advanced experience on this head augurs but indifferently for the future of this cable, which certainly should be in every respect more perfect than any heretofore submerged.

I will, secondly, briefly refer to the insulation of this cable, which consists of alternate layers of gutta-percha and Chatterton's compound, the latter, of course, being but an admixture of the former with other materials; and, although superior in some respects, yet taken as a whole it were safer to insulate with percha only. The choice thus made for insulation, I need scarcely say, has surprised every one, not excepting those immediately interested in the manufacture of gutta-percha, for, like candid and honest men, they are free to admit the feasibility of the objection urged to its use in warm climates. As is the conductor, so is the insulation, a departure from acquired experience, denoting an inexcusable retrograde step, which all previous enterprises in this direction but too well confirm. With the fate of sundry other cables before our eyes, one may *wish* that this may be a success, but scarcely dare hope that it will rank any higher than the Rangoon, or the Red Sea cables. In addition to the utter inability of percha to withstand high temperatures, it is also of too non-elastic a nature to bear the strain which will be thrown upon it by the means above referred to, without serious injury. And thus this material, which is a really good insulator in ordinary circumstances, is not unfrequently made to bear the ill-repute which is justly due to the irrational construction of the outer sheathing, and hence, if it had a tongue, it might cry out, "Save me from my friends." The force of opinion insisted on caoutchouc insulation in this case, but it has been disregarded, and it may well be asked in whom are we to put our trust for the successful working out of this problem of ocean telegraphy, since the results of progressive experience are ignored?

3rdly. As to the outer covering. This matter has been also ably treated by certain of your correspondents, in every way capable of forming correct opinions, as to leave me nothing to say on this head, save a few remarks, which must also be in the same censuring strain as the preceding. The cable, of course, is to be sheathed with iron wire, in the usual way, and will consist of 12 No. 7 gauge for that part which is to be submerged in deep water, after which there are to be repeated coverings of the whole, in order to protect the iron from rusting too speedily, consisting alternately of a serving of mineral pitch, silica, and Stockholm tar, and yarn, the former mixture to be put on boiling hot, rather a risky process, one would imagine, to so susceptible a material as the gutta percha, which lies immediately beneath. This additional protection of a protector, by the way, is a patented process of Mr. Latimer Clark.

It will thus be seen that the Persian Gulf cable, when completed, will weigh not far short of 4 tons per nautical mile, if indeed, it do not exceed that weight. This fact speaks for itself, I need say no more. We shall be more surprised at its success than its non-success. Think of four tons per nautical mile, and the amount of elongation that will ensue, risking the disjunctibility of the core, and the strain to breaking point on the conductor, and having the fate of other cables before our eyes, how can we be at all sanguine of the success of this one, or refrain from condemning the manufacture of cables upon such principles that must inevitably tend to ruinous failure and expense, and no less tend to the retardation of submarine telegraphic success. PHILO.

Gossip.

We regret that we have to record the death of Mr. Weale, of High Holborn, which took place on the 18th inst. Mr. Weale was a most enterprising publisher, and the valuable works that issued from his establishment have materially contributed to the progress of science and art in England. He risked £50,000 on his "Rudimentary series" alone. He expended, at his own risk, £209,502 on his publications, and £29,695 at the risk of authors.

The *Prairie Farmer* says that we are in a fair way to obtain from sorghum a valuable material for the manufacture of paper. A paper mill on the Fox river, Ill., is already using considerable quantities of it in the manufacture of wrapping paper, and is putting in the necessary machinery for preparing it for printing paper. When completed, it will use from two to three tons of sorghum per day.

Admiralty orders have been received at Chatham Dockyard, directing that steam-vessels of war of every description, with the exception of gunboats, are to be fitted with engine-room telegraphs.

The *Moniteur de l'Armee* publishes a regulation emanating from the Ministry of War, relative to the prevention of accidents by fire. The use of the ordinary chemical matches is interdicted in barracks and other military establishments. The "Allumettes hygieniques armophes" are alone authorized. Soldiers, or other persons employed in the above places, who infringe this regulation, will be severely punished.

The Government have selected the tender of Mr. Henley, the sub-marine contractor, of North Woolwich, for the manufacture of the Persian Gulf telegraph cable, which is to be 875 nautical miles in length.

It is said that a plan has just been tried on the Northern Railway of France for receiving the letter bags at intermediate stations without stopping the train. By means of a ring the bag is attached to a post on the line; the engine is provided with a rod, so disposed as to catch the ring, and thus carry off the letters. By a similar contrivance, bags are left by the train when necessary.

An experiment, says the Paris correspondent of the *Times*, was made a few days since at Nancy with a new propeller on a temporary railway constructed with rails lent by the directors of the Paris and Strasburg Railway Company. Several persons of distinction, and many others interested in railway concerns, were present. As the inventor asserts that his propellor is capable of exerting the greatest force, and of propelling railway carriages at the greatest speed, the question of force alone was the subject of the late experiment. As the road was prepared so as to present the greatest difficulties, such as an ascent of three centimetres the metre and two successive curves of a radius of 60 ft., it would have been dangerous to proceed at a greater speed than that of an ordinary French train (about 35 miles an hour). It is further to be remarked that the rails lent by the Strasburg company were not in a very good state. The ends of the rails were so uneven that even at the moderate speed at which it was driven the waggon was much jolted. The success of the experiment was complete as to the regularity of the action of the propeller. It was admitted by all present that the motion was uniform and without any sudden shock.

The same newspapers that describe a visit of the Emperor of France to Baron James de Rothschild, state that the Bavarian Government has refused to ratify the election of a Jew to an academic chair.

We read in a Copenhagen letter:—The Royal Artillery, some days ago, made experiments with gunpowder made of paper, which turned out a success. Common packing paper was, in the course of 10 or 15 minutes, transformed into a very powerful kind of gunpowder, and a number of different shots were fired with it. The invention, which seems to be very interesting, belongs to a foreigner.

According to "My Diary, North and South," by Mr. Russell, of *The Times*: in the Washington Navy-yard, this gentleman had the advantage of a colloquy with Captain Dahlgren, who contrived to show him such good practice with shrapnel, and to fire so rapidly, as to keep three shells in the air at the same time.

MINERAL TRAFFIC ON RAILWAYS.—The total quantity of minerals carried on railways in the United Kingdom last year amounted to 63,604,434 tons. Of this vast total, the London and North Western carried 5,381,326 tons; the North Eastern, 6,979,524 tons; the Caledonian, 3,506,672 tons; the Midland, 4,129,910 tons; the Great Eastern, 709,986 tons; the Great Northern, 1,498,654 tons; the Lancashire and Yorkshire, 2,655,498 tons; the Manchester, Sheffield, and Lincolnshire, 611,261 tons; the Great Western, 2,441,118 tons; the Blyth and Tyne, 1,562,068 tons; the Furness, 676,863 tons; the Londonderry, 666,250 tons; the Monmouthshire, 1,603,274 tons; the Newcastle and Carlisle, 627,877 tons; the North Staffordshire, 625,959 tons; the Rhymney, 1,253,891 tons; the St. Helen's, 870,058 tons; the South Wales, 1,455,847 tons; the South Yorkshire, 1,016,639 tons; the Stockton and Darlington, 3,706,144 tons; the Taff Vale, 2,574,446 tons; the Vale of Neath, 776,765 tons; the West Hartlepool, 1,800,981 tons; the West Midland, 897,651 tons; the Whitehaven, Cleator, and Egremont, 514,495 tons; the Edinburgh and Glasgow, 1,341,514 tons: the Edinburgh, Perth, and Dundee, 513,756 tons; the Glasgow and South Western, 2,475,326 tons; and the Monkland, 1,603,369 tons. The 63,604,434 tons conveyed produced the companies £5,191,193. It will be perceived that, of companies which conveyed less than 500,000 tons in the 12 months, no account has been taken.

AN ILLUMINATING BOMB.—A French lieutenant of Artillery has lately tried, at Namur, a new projectile of his invention. It is intended to light up at night any place it is wished to reconnoitre. The light of the new bomb has shown itself to be very powerful, and it illuminated a radius of several hundred metres. Two or three similar projectiles would be sufficient to light up a plain of very great extent.

THE GOVERNMENT STEAM-RAM, "HECTOR."—This vessel, which was launched from the building yard of Messrs. R. Napier and Sons, Govan, in September last, having nearly completed her armour-plating, arrangements were made on Wednesday, the 17th inst., for having her towed to Greenock by the Sunday morning tide, where she will be berthed in the Victoria Harbour, and at the same place occu-

pied by the "Black Prince" last year. In the harbour at Greenock the "Hector" will receive her machinery and boilers, and be otherwise fitted for sea. Her draught of water is now about 21 ft. The dimensions of the "Hector" are 286 ft. long, 56 ft. broad, and 38 ft. deep, her tonnage being 4,063. She will be propelled by a pair of horizontal engines of 800 horse-power, prepared by the builders, and fitted with a screw. Her masts and bowsprit will be iron, and the latter will be constructed so as to double up when necessary. The cost of her hull alone will be over £170,000. The "Hector" will carry twenty-four 68-pounders, and six 110-pounders on the main deck, with a 110-pounder pivot-gun on the upper deck at the stem and stern. Her iron-plating of 4½ in. thick will extend to a depth of 5 ft. below the water-line. Another vessel named the "Valiant," nearly similar in every description, is also in course of construction at the Admiralty Yard, Isle of Dogs.

THE ROYAL AGRICULTURAL SOCIETY.—The next meeting of the Royal Agricultural Society will be held at Worcester, and the time has just been arranged for the week commencing July 20. The site selected for the exhibition is in the immediate vicinity of Worcester, on the Battenhall property, belonging to Sir Thomas Sebright. The ground selected for the showyard has all just been levelled and drained. The extent is 39 acres, and the fields for ploughing, reaping, mowing, and other agricultural operations, which are near at hand, are, together, above 100 acres more. A branch will be run out of the West Midland Railway, which passes near, into the show ground. The amount subscribed by Worcestershire for the necessary expense of the meeting is £4,720. The special prizes are not yet arranged.

Patents for Inventions.

ABRIDGED SPECIFICATIONS OF PATENTS.

THE Abridged Specifications of Patents given below are classified, according to the subjects to which the respective inventions refer, in the following Table. By the system of classification adopted, the numerical and chronological order of the specifications is preserved, and combined with all the advantages of a division into classes. It should be understood that these abridgements are prepared exclusively for this Magazine from official copies supplied by the Government, and are therefore the property of the Proprietors of this Magazine. Other Papers are hereby warned not to produce them without an acknowledgement:—

STEAM ENGINES, &c., 1576.
BOILERS AND FURNACES—*none.*
ROADS AND VEHICLES, including railway plant and carriages, saddlery and harness, &c., 1569, 1587, 1609, 1628.
SHIPS AND BOATS, including their fittings, 1586, 1590, 1595, 1599, 1601, 1618.
CULTIVATION OF THE SOIL, including agricultural implements and machines, 1573, 1577, 1578, 1627.
FOOD AND BEVERAGES, including apparatus for preparing food for men and animals—*none.*
FIBROUS FABRICS, including machinery for treating fibres, pulp, paper, &c., 1570, 1597, 1606, 1614, 1615, 1620, 1621, 1624.
BUILDINGS AND BUILDING MATERIALS, 1574, 1604, 1616.
LIGHTING, HEATING, AND VENTILATING, 1575, 1580, 1602.
FURNITURE AND APPAREL, including household utensils, time-keepers, jewellery, musical instruments, &c., 1572, 1584, 1593, 1600, 1603, 1610, 1612, 1619.
METALS, including apparatus for their manufacture, 1607.
CHEMISTRY AND PHOTOGRAPHY, 1611.
ELECTRICAL APPARATUS, 1581, 1583, 1626.
WARFARE, 1571, 1589, 1592, 1622.
LETTER-PRESS PRINTING, 1579.
MISCELLANEOUS, 1582, 1585, 1588, 1591, 1596, 1598, 1605, 1608, 1613, 1617, 1623, 1625.

1569. M. WALLS, and J. CROMPTON. *Improvements in railway signals.* Dated May 26, 1862.

This invention is for the purpose of putting on and taking off railway signals, and also for shewing the time that one train has passed to the next train coming on the same line, or when the machine is placed, and to warn a following train of the danger. The patentees fix a pump or cylinder, with the necessary clack piston and tap, in any convenient position to the semaphore or signal post, and feed the pipe and cylinder with any suitable liquid or air. They connect the semaphore to the piston of the pump by a connecting rod, or other suitable means, and the connection between the rails and the pump is accomplished by transverse levers, so that, when an engine or train passes over the rails opposite the semaphore, it acts on one of the transverse levers by means of a tongue or other apparatus, and by pressing down the lever the arms of the semaphore are set in the horizontal position; and at any convenient distance from the said lever they place another transverse lever, which being pressed down by the weight of the carriage, the same as already described and being connected with it by wire or other convenient means, the arms of the semaphore are liberated, and fall; but instead of falling suddenly, they can be regulated to fall at any required degree of motion, according to the pressure of the liquid or air acting on the piston of the pump, thus falling gradually they will not be in the vertical position until the proper time as regulated by railway companies for one train to follow another. And by means of a graduated dial and pointer, they can indicate the exact time between the arms of the semaphore being set and released. And to prevent a sudden pressure on the lever or levers as the weight passes over them, they use a spring, or any elastic substance between the rails and the levers. *Patent completed.*

1570. J. TAYLOR. *Improvements in preparing cotton or other fibrous materials to be spun.* Dated May 26, 1862.

This invention relates to the carding engine, and consists, 1. Of improved modes of giving the to and fro motion to revolving knives or combs. The said knives or combs at each end work loosely, in a stationary, excentric slot, so that, as they revolve, they project, one after the other, beyond the periphery of the roller which contains and propels them, in order to strip the doffing cylinder, and then recede, one after the other, in their slots or grooves. 2. In the application of an angular or other shaped bar intervening between the fibrous material on the doffer of the revolving combs or knives. The patentee applies the said bar for the purpose of consolidating the material on the doffing cylinder, and for preventing the combs from taking it off unequally. 3. In the application of adjustable stop pieces to each end of the loose combs, for the purpose of allowing the said combs to be adjusted separately. 4. In the application of a jet or blast of air adapted so as to act on the selvedges of the sliver, and protect it from being made into waste. And, 5, In the application of an electric band, or an equivalent, for keeping the knives or combs in contact with the inner eccentrics. *Patent completed.*

1571. W. BRIERLEY and G. F. SMEETON. *Improvements in apparatus connected with targets.* Dated May 26, 1862.

Here the inventor uses a rod, carrying a flag or signal, balanced in such a position that the signal will be a little below the upper part of the target, and invisible to the firing party. The whole is nicely balanced by a weight on the signal rod, so that, upon the bull's-eye disc, or plate, on the lower rod being struck by a shot, the shaft working on centred lags, will oscillate freely. The rod carrying the signal, being secured in the boss of the same shaft, will also oscillate, in the manner of a scale beam, or pendulum, until the motion is overcome by its gravity. Two springs are placed on the target for the rods to strike against at each oscillation. The invention also relates to the construction and form of plates to be used as centres, which are made of wrought iron, cast iron, or other suitable metal, in the form of a gong, or disc, or plate, having a bell-mouthed rim thereon; or these plates may be square, with the rim on, as described. The centres are suspended in front of the target, and, when struck by a shot, produce a sound which differs in tone from that of any other part of the target when struck. *Patent abandoned.*

1572. W. CLARK. *Improvements in fastening buttons to garments and other articles.* (A communication.) Dated May 20, 1862.

This invention is not described apart from the drawings. *Patent abandoned.*

1573. W. WORBY. *Improvements in reaping machines.* Dated May 26, 1862.

The patentee claims, 1, So constructing reaping machines that the platform and cutting parts may be turned up, so as to allow of the whole machine passing freely through an ordinary field gateway, and, when the platform and cutting parts are turned down for use in the field, the joints upon which they move allow of rise and fall, according to the unevenness of the land. 2, Causing a series of rakes, or other similar instruments, which, in their rotary action, by being brought in contact with a series of suitable cam surfaces, are caused to act as an ordinary fly for laying the corn, and afterwards removing it, when cut, at the sides of the platform and cutting parts, by suitable mechanical connections, between the platform and rakes, or delivery apparatus, so as to maintain their proper relative position with respect to the platform surface. *Patent completed.*

1574. J. A. C. N. DELPECK. *Improvements in pumps.* Dated May 26, 1862.

This pump, which is of an entirely new principle, may be placed either in a horizontal or vertical position. In both cases it is double acting, *i.e.*, the piston produces at once a vacuum on one side, whilst it forces the water on the other side. In both arrangements the apparatus is composed of an external metallic casing, divided into two distinct portions, the one containing the cylinder in which the piston moves, and which is called the cylinder chamber, whilst the other contains four elastic balls, acting as valves, or clacks, and is called the ball chamber. The cylinder chamber itself is divided into two parts by a vertical partition, or diaphragm, according as the pump is a horizontal or vertical one. In both arrangements this partition is provided at its centre with a round opening, for the cylinder that passes through the same, and on which it is fixed. The tight joint of the cylinder in this partition separates thoroughly the two compartments, which communicate by the interior of the cylinder in which the piston moves. The cylinder is open at both ends, and between its extremities and the chamber ends a space is left for the circulation of the liquid contained in these vessels. The ball chamber is also divided, internally, into two equal compartments, by a vertical partition. Each of these compartments, however, communicates by a wide opening with one of the compartments of the cylinder chamber. *Patent completed.*

1575. R. M. LETCHFORD. *An improvement in the manufacture of matches.* Dated May 26, 1862.

The object of this invention is to produce matches, at a low price, free from sulphur and from objectionable smell. The invention consists in dipping the ends of the usual match splints in, or in saturating match splints with, petroleum, or rock oil. The splints, having been thus prepared, are dipped into any of the ordinary lighting compositions. *Patent completed.*

1576. G. A. HUDDART. *Improved means for superheating steam.* Dated May 26, 1862.

Here the patentee withdraws the steam from the boiler by the aid of a force pump, and discharges it, under pressure, into a superheating chamber, or oven, which receives its heat from a furnace, or furnace flues, into which it is so built that the flame and heated gases may play around it. This superheater he proposes to fit with a series of parallel copper tubes, somewhat like those in a locomotive engine, through which the gases of combustion will pass. *Patent completed.*

1577. J. E. HOLMES. *Improvements in machinery for digging or cultivating land.* Dated May 26, 1862.

This relates to an arrangement and mode of operating a series of spades, prongs, tines, or digging instruments, which are made to enter or penetrate the earth in succession as they are drawn over the surface, and, having penetrated the land, are caused to lift up and turn over the earth, and in so doing to disintegrate and break up the clods. *Patent abandoned.*

1578. J. E. HOLMES. *Improvements in machinery for digging or cultivating land.* (A communication.) Dated May 26, 1862.

This consists of a rotary digging or cultivating implement composed of a strong horizontal shaft, provided with a series of screw blades of from ten to twelve inches in depth, and which are wound at a suitable angle helically round the shaft. This shaft is mounted in bearings at the end of a pair of rocking levers, which have their fulcra on the axle-tree of the running wheels, and rotary motion is communicated to it by a pulley or chain wheel on one end of the axle. The other end of the rocking levers are connected to a bar or block through which passes a vertical screw shaft, by turning which one end of the levers are raised or depressed, and the opposite ends, which carry the shaft of the digging implement, are depressed or elevated when desired. The outer ends of the rocking levers are also provided with quadrant arms, in which are made holes to receive pins, whereby the rocking arms and digging instruments may be kept at any point of depression or elevation required. In front of the rotary digging instrument is placed a series of coulters, which may be raised and depressed with the rotary digging instrument. On the axle of the travelling wheels of the machine, or on the wheels themselves, are fixed two spur or chain wheels, round which, and also round the pulley on the axle of the digging instrument, are passed chains for driving the same. *Patent abandoned.*

1579. J. E. HOLMES. *Improvements in printing machinery.* (A communication). Dated May 26, 1862.

This consists in an arrangement of parts whereby a press for job work may be constructed in such a manner as to be capable of being worked by means of a treadle or winch handle, or by power. *Patent abandoned.*

1580. J. D. T. SPARROW. *An arrangement or arrangements for shading street lights, and in order to protect or shade the eyes of riders and foot-passengers from the dazzling effect of the flames of such lights.* Dated May 26, 1862.

Here the inventor attaches to the street lights metal or other shades, either whitewashed on the side nearest the flame, or fitted with reflecting surfaces, the shades and reflecting surfaces being of such form, and placed at such angle, as to render the flame invisible at the distance of one lamp-post from the next. And he makes such shades either circular (as for lamps or lights at corners or turnings), or portion of square shades, containing one, two, three or four sides, according to the effect desired at each particular spot. *Patent abandoned.*

1581. E. TUCK. *Certain improvements in electrical manipulation applicable to submarine telegraphs.* Dated May 27, 1862.

In place of the present method of completing circuit through the sea, the inventor makes use of the exterior of the iron wire covering of the cable, to which he affixes a covered conducting wire, which is brought into contact with the interior conducting wire of the cable by the instrument for receiving a message. In conveying or delivering a message, this contact is broken, and he makes use of a sheet or piece of zinc (in place of copper) in contact, or placed in the sea, to which is annexed a covered conducting wire, brought into contact with the copper or negative plate of a voltaic battery; this is effected by the recording telegraph instrument, as at present in use. *Patent abandoned.*

1582. C. A. M. DURAND. *A new kind of watermill.* Dated May 27, 1862.

This consists, 1, Of a large basin, or reservoir, fed from a source which, however slight, will allways suffice to maintain the same level of water. The bottom of the basin will be constructed of sandstone, or rough masonry, and covered with slabs of stone, in order to preserve the water, if the supply be limited. 2, Of the pumps which serve to raise the water from the large basin to another fixed above, these pumps being of sufficient force to furnish, together, the quantity of water necessary to turn two stones. 3, Of a second basin, or reservoir, intended to receive the water raised by the pumps, the water falling from them by a conduit upon a large wheel placed beneath. 4, This large wheel, which receives motion by the water falling upon it from the upper reservoir, communicates it, by a horizontal shaft, to the small stones, which are on each side, and, at the same time, to two perpendicular shafts, which work the pumps, so that the entire system is animated by a regular and constant movement, the quantity of water falling on the wheel being always the same, and the pumps re-raising incessantly the water necessary to cause the mill-stones to turn. *Patent abandoned.*

1583. W. E. GEDGE. *Improvements in the manufacture of wire rope or cables.* (A communication). Dated May 27, 1862.

The wire rope or cable forming the subject of this invention differs from those ordinarily made in a most essential point. The six strands, instead of being twisted all to the

right, or all to the left, are twisted three to the right and three to the left, or reciprocally. There are, therefore, three different and equal forces in constant opposition, which naturally destroy or negative each other; hence the equilibrium, or, rather, immobility of the cable, and this constitutes the base of this invention. *Patent abandoned.*

1584. J. HALLIDAY. *Improvements in the manufacture of ornamental trimmings.* Dated May 27, 1862.

In carrying out this invention the inventor cuts by hand, or punches any fabric to a required design, and fills up the insterstices, or parts cut out, with a different material, or uses one material only, and sews the two materials together either by hand or machine, and secures the two together by stitching. *Patent abandoned.*

1585. J. IRELAND. *Improvements in forming moulds for card cylinders.* Dated May 27, 1862.

This consists in using an expanding and contracting core barrel for the card cylinders of carding engines, and coating them with loam in the following manner:—The patentee places the barrel, when expanded to its full size, upon a turn-table, and causes it to revolve past one or more sweeps attached to one or more slide rests, for the purpose of acting upon the loam as it is placed upon the barrel, and regulating the size of the core. He also uses a sweeping frame, having one or more spaces in which a sweep is moved, so as to form spaces in the core for the thickening ribs of the card cylinder. In connection with the aforesaid core barrel, he uses an outside box or casing coated with loam in the inside by a sweep attached to a slide rest. When the core or casing are finished and dried, they are placed upon a plate which is made perfectly true, and when thus put together the space between them will form the cylinder when the metal is run into it. After casting in the usual way, the core barrel is contracted and drawn out so as to allow the cylinder to contract. By these means card cylinders require no balancing, and are made with greater truth and in less time than by other means. *Patent completed.*

1586. H. D. P. CUNNINGHAM. *Improvements in anchors.* Dated May 27, 1862.

This invention consists in constructing the arms of anchors to terminate in a "pick," or penetrating bar, similar to that of an ordinary pickaxe, and in forming a fluke or broad holding surface at the inner end of the pick, and between it and the shaft or shank. The pickaxe termination of the arms will ensure penetration, while the fluke or broad surface thereof or thereon will impart great holding power. In weighing, also, the particular construction of the arm will enable it readily to break out of the ground. *Patent completed.*

1587. W. CLARK. *Improvements in brakes for railroad carriages.* (A communication.) Dated May 27, 1862.

Here the inventor employs a tumbling rod, placed longitudinally under each car just above its axles, the tumbling rods of the several cars comprising a train being connected together, and so arranged that they, with their draw bars, may be rotated and also lowered and raised; and by suitable gearing connected with a slide and belt shipper, the above parts being used in connection with two cones, a belt, and two cylinders, one cone and cylinder placed on an axle of each car, and the other cone and cylinder on a lever, which is connected to a chain attached to the brake bars. By these means the brakes may be applied by a single person to all the cars in a train simultaneously. *Patent abandoned.*

1588. F. TOLHAUSEN. *Applying various mineral and organic substances to wire gauze, and metallic asbestos tissues, for rendering said tissues available for ornamental and useful purposes.* (A communication.) Dated May 27, 1862.

This consists in filling up the interstices in tissues of the kind above named, with compounds of transparent and opaque substances, which may be coloured by means of gum lac colours mixed with varnish or gelatine, and by which process the patentee renders the said metallic or asbestos tissues fit to be used for ornamental purposes, such as blinds, signs, lamps, and lanterns, and so forth. *Patent completed.*

1589. G. SANBORN. *Improvements in revolving breech-loading firearms.* (A communication.) Dated May 27, 1862.

This relates to a novel construction and arrangement of the parts of the frame of revolving breech-loading firearms. The barrel is of the ordinary construction, and may be either rifled or smooth bore. The frame into which the barrel is screwed is of dimensions to contain the cartridge cylinder, and is fixed upon or constructed as a part of the stock or handle of the firearm. This frame, which is made in parts, has a hinge joint situated upon its upper side and near the rear end of the cartridge cylinder, and at its diagonal corner a spring catch or lock, which, in connection with the said joint, firmly receives the frame. The cartridge cylinder, which has a recess in front, revolves upon a spindle or rod fixed in the front part of the frame, and the rear end of said cylinder fits into a chamber which constitutes a portion of the frame. In the centre of this recoil chamber is a circular or ring-formed recess, which receives, when the frame is locked, a projecting ratchet, by which the cylinder is revolved, and which constitutes a part of the said cylinder. The interior of this recess is left flush with the surface of the recoil chamber, thus forming a pin, which enters the rear end of the cartridge cylinder to secure the same firmly during the discharge of the pistol or gun. The ordinary means in connection with the ratchet on the cylinder are used for rotating the said cylinder. *Patent abandoned.*

1590. J. HAY. *Improvements in war ships, also applicable in part to land and floating batteries, or forts, and in part to mercantile and other vessels.* Dated May 27, 1862.

We cannot here quote the details of this invention. *Patent abandoned.*

1591. J. DUFFUS. *Improved apparatus for measuring piece-goods or webs.* Dated May 27, 1862.

This apparatus comprises a roller, round, or partly round, which the article is made to pass, and the spindle of which communicates by a wheel-work train with the index of a dial, showing yards or other desired measure, provision being made for winding the fabric upon a roller, board, or spindle, by means of a crank handle. Provision is also made for pressing the fabric closely in contact with the measuring roller, so as to insure the accurate turning of this roller, and its correct measuring completely to the extreme end of the piece passing through. *Patent completed.*

1592. W. PALMER. *Improvements in revolving firearms.* Dated May 27, 1862.

This invention consists, 1, In the employment of a carrier intermittently revolved by suitable automatic mechanism, and presenting a loaded chamber at the rear of the barrel, pausing while the charge is fired, then proceeding on by the said mechanism, and presenting another chamber on the line of the barrel, the previous discharged chamber being allowed to drop out of the said revolving carrier. 2, In combining with the said revolving carrier a hopper slide or opening, so located on a plane parallel, or nearly parallel, to the axis of said revolving carrier that the said chambers shall, by their own gravity, descend into the grooves provided in the said revolving carrier, as such grooves are successively presented for the reception of the said chambers. 3, In combining with the said revolving carrier a shield or casing to retain the said chambers in the revolving carrier from the point at which they drop from the said hopper slide or opening until they have been fired, after which the said chambers are allowed to drop away by their own gravity. 4, In the employment of a revolving cam in connection with the said rotary carrier, the said cam being so formed as to allow the necessary pause for the discharge of each chamber, or brought opposite to the barrel, the said cam also acting to hold the carrier and the chamber so that the chamber is on the line or the barrel when fired. 5, In the employment of automatic mechanism to press the chambers to the rear end of the barrel after being brought to line with the barrel by the aforesaid rotary carrier, so as to prevent the escape of gases, &c. 6, In the combination with a detached section of a barrel or chamber of a metallic cartridge, so formed that the metallic case of the said cartridge enters the rear end of the barrel when pressed forward, as aforesaid. 7, In constructing the mechanism that rotates the carrier in such a manner that a hammer is liberated to explode detonating powder and fire, the piece at the bind of the said carrier is stationary, and then recock the hammer before the carrier commences again to move the rotary automatic mechanism, giving these relative movements to the hammer, and the carrier being unchecked in its revolution. 8, In the mechanism employed for giving end motion to the said carrier. 9, In the means for moving the chambers with the carrier in its endwise action. 10, In the mechanism for revolving the carrier. *Patent completed.*

1593. D. T. MOSS. *Improvements in fastening horse-shoes.* Dated May 27, 1862.

For the purposes of this invention, horse-shoes are made in the ordinary manner, and of the usual forms, and to each shoe two thin metal straps are applied, by peference of steel; one end of each of these straps is fastened to the fore part of the shoe, but at some distance apart, so that when these straps are crossed on the front of the hoof, the point of crossing is on the front and between the top and bottom of the hoof. The fastening of the front ends of these metal straps to the shoe is, by preference, by means of screws, but, when the desired fastening has been obtained, the ends of the screws are rivetted, or upset, so that they may not become loose. At the heel of each shoe, opposite the inner and outer quarters of the hoof, there are applied two lugs, or plates, which rise to the upper part of the hoof; one of these, it is preferred, should work on a hinge joint. These plates, or lugs, have holes through them at their upper ends, through which short tubes (which are fixed to the back ends of the metal straps) pass. The short tubes are formed with internal, or female screws, which receive male screws with spreading heads, by which the ends of the metal straps are retained in their positions. These short tubes also receive the ends of a vulcanized india-rubber strap, which is applied at the back of the hoof. The holes through the ends of the india-rubber strap, through which the short tubes pass, are strengthened with metal eyelet holes. *Patent abandoned.*

1594. G. H. DAW. *Improvements in firearms.* Dated May 27, 1862.

These improvements are applicable to the breech-loading firearm described in the specification of a patent granted to Francois Schneider, dated the 11th day of June, 1861 (No. 1,487). In order that the lever for bolting the barrels, and which works in a vertical direction, may, when the barrels are in place, be securely held under the trigger guard, the patentee joints to it a small catch; this catch has a projection on it, and, when the lever is up under the trigger-guard, it enter a hole or recess therein; a spring, with which it is fitted, keeps it up. To open the breech, it is necessary only to press on the catch to cause its spring to give way, so as to withdraw the projection from the hole or recess, and free the lever. This improvement is also applicable to other breech-loading firearms in which the lever works vertically, and lies along under the trigger-guard when out of use. Another improvement relates to the manner of securing the barrels to the fore part of the body, as described in the specification of Schneider's patent; there is a projection on the barrel lump which enters a recess in the fore part of the body. Now the patentee finds it more convenient to reverse this arrangement, and to form the projection on the fore part of the body, and the recess in the barrel lump. He prefers, for the sake of adjustment, that the projection should be a screw, as formerly. This improvement is applicable in other breech-loading arms, in which the fore part of the body is jointed to the hinder part by a joint independent of the barrels. Another improvement on the arrangement described in the specification of Schneider's patent consists in taking the strains produced by the explosion off the joint, by means of a bar introduced across the recess into which the barrel lump fits. The barrel lump is notched, to take the bar, which may either be made in one piece, with the body, or the body may be drilled, and the bar tapped or driven into it. This arrangement is also applicable to other breech-loading firearms, in which the body is similarly constructed. Another improvement in the arm described in the specification of Schneider's patent, has for its object the preventing the slide, which expels the exploded cartridge, from being drawn out of its place when the breeches are open, or when the barrels are removed from the stock, and consists in applying projections to the forked ends of the slide, which, coming against the guides, stop the slide when it is out as far as it ought to come. The slide may still be removed for cleaning, by springing the forked ends of the slide apart; this improvement is applicable in other cases in which slides of this description are applied. Another improvement, applicable to the arm described in Schneider's patent, and other arms in which the cartridge contains the fulminating material, consists in working the pistons, which receive the blow of the hammer, and explode the cartridge by means of straight, in place of spiral, springs, and thus greater durability and certainty of action is obtained. Another improvement on the arm, described in the specification of Schneider's patent, and other breech-loading arms, in which there is a joint between the barrels and stock, consists in applying a connecting link behind the joint, so as to connect the breech ends of the barrels with the stock, in order that, in opening the breech, the link or lever may retain the barrels when they have moved a sufficient distance, and thus the great strain, otherwise thrown on the joint, is avoided. Another improvement consists in an arrangement of the back sight of firearms, and consists in connecting the slider to the bed by a link, jointed to the slider at one end, and capable of sliding along the bed at the other end in a slot, or way, formed for it. This link serves both to keep the slider in place, and to prevent light being seen beneath it. *Patent completed.*

1595. O. H. HUDSON. *A defensive armour.* Dated May 27, 1862.

This invention consists, chiefly, in the use of certain means, appliances, and arrangements, for the purpose of lessening the percussion of projectiles upon the backing or supports of metallic armour by the introduction of water between the said supports and the protecting armour, and also around its fastenings. The patentee effects this by covering the surfaces exposed to the action of projectiles with a metallic structure of a cellular form, presenting a strong surface to the action of the projectile, and from its construction capable of holding and retaining water within its cells, or between its inner surface and that of the supports or backing. This arrangement or system of defensive armour is applicable to all kinds of objects, whether moveable or fixed, on land or water, although chiefly applicable to ships. The beneficial results to be obtained from the introduction of water between the armour plates and their supports are based upon two well-known properties of water, viz., its almost total incompressibility, and its power of transmitting force equally and in every direction. He prefers that the water should be distributed, whether within or behind the structure of the armour, in divisions or compartments, so that the destruction of any one division would not materially affect the perfect action of the others. In carrying out the principle of introducing water in compartments between the supports and the armour, or within the structure of the armour, several methods may be adopted, but those which he prefers as part of this invention are illustrated in the drawings. *Patent completed.*

1596. H. EATON. *Improvements applicable to presses for baling purposes.* Dated May 28, 1862.

This invention relates to that part of baling presses termed the "stillage," which is commonly formed of a bed of wood faced with metal plate, and provided with grooves to enable the hoops or ropes to be secured round the bale when pressed. As various sizes of bales are required to be made up in the same press, these common "stillages" have to be changed, and as many stillages are required to each press as there are changes in the distance between the hoops or ropes on the bale to be made up. Now this invention relates to a mode of constructing a universal stillage, practically applicable to every size or distance between the hoops or ropes to be placed on the bales, and it consists of a bed secured to the press in the ordinary manner, this bed being faced with a plate of iron which overhangs the bed at opposite sides, and is provided with a series of slots for securing a series of ribs close against each other, so as to cover the entire surface of the bed. Buttons or T-heads from the ends of the ribs enter the slits or slots in the plate, and are thus held up, the ribs being kept in their places by a catch or bar. With this improved stillage each or any of the ribs can be removed or replaced, and the stillage can be prepared for any size of bale by removing those ribs which come opposite those parts of the bale where the hoops or ropes are required, and by replacing those ribs which may have been previously removed. The mode of securing the ribs may be variously modified; the ends may be secured in slots, or grooves, or otherwise. *Patent completed.*

1597. J. H. KIDD. *An improved manufacture of compositions applicable for waterproofing fabrics for coating and protecting various articles, and for various other purposes.* Dated May 28, 1862.

The patentee claims, 1, A composition formed by the combination of oxydized oil, and a base formed of wax, mutton suet, and resins, and such colouring matters as may be required, as described. 2, A composition formed by a combination of his india-rubber or gutta percha, with wax, mutton suet, and resins, as described. *Patent completed.*

1598. J. SIMPSON. *Improvements in machinery or apparatus for cutting or producing mouldings upon surfaces of wood or other suitable material.* Dated May 28, 1862.

This invention consists in a heavy bar of metal or wood supported upon a shaft at the end of its length, such shaft having bearings on a suitable framing. At one or each end of this bar or block a blade or cutter is secured, so formed as to cut the material under operation into the form or

moulding required, the bar being caused to rotate by means of a handle on the centre shaft, a self-acting feeding apparatus being provided to propel the wood. The action of the cutters upon the material partakes of a chipping nature, the chief feature in the invention being the distance of the cutter from the centre of support, whereby there is more leverage obtained and greater steadiness effected in the cutting, the high velocity of revolution not being required as in smaller cutters. *Patent completed.*

1599. J. Rogerson. *An iron floating dock to be used for the purpose of building and repairing ships, steamers, barges, and floating vessels of all descriptions.* Dated May 28, 1862.

We cannot here quote the details of this invention. *Patent abandoned.*

1600. C. Cohen. *Improvements in walking umbrella and other like sticks.* Dated May 28, 1862.

This invention consists in the mode of making and securing the handle of canes or sticks of all descriptions. The cane is split down the middle about six to twelve inches, and a wedge-shaped piece of wood, ivory, or other like material is inserted of the shape and form desired; the two halves of the cane are then bent round and glued, or cemented to the handle, and follow the shape of the same. The handle has thus a flexibility and strength, which prevents its breaking on letting it fall or receiving a sudden blow as the stock is distributed in the cane. *Patent completed.*

1601. J. F. Harrison. *Improvements in preserving the bottoms of ships from the attacks of carbuncles and other like incrustations.* Dated May 28, 1862.

In carrying out this invention the patentee applies to the bottoms of ships or vessels plates or sheets of wrought iron, or cast iron, or other metals or admixtures of metals, or slate covered with vitreous glaze, or enamel fused at a high temperature, or with water, glass, or silicate of soda or potash, which latter may be applied either direct to the bottoms of ships, or on plates or slabs to be affixed thereto. These covered sheets or slabs are to be affixed to the bottoms of vessels or ships, by and of marine glue, or other suitable glue or adhesive mixture, or by the aid of Portland cement, or other cement, or by screws, rivets, or other fastenings. *Patent completed.*

1602. R. Martindale. *Improvements in the manufacture of globes and glasses, more particularly applicable to hydrocarbon and spirit lamps, and also in fastenings for securing the globes or glasses in those and other descriptions of lamps.* Dated May 28, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1603. T. Turner. *Improvements in machinery for scouring and polishing knitting and other pins and needles.* Dated May 28, 1862.

The knitting or other pins or needles to be polished are placed and held for part of their length between clamps or surfaces, one of which is pressed down by spring pressure, or other suitable means, with sufficient pressure to retain the pins, and at the same time to admit of their rotating by the to and fro sideway movement of the upper clamping plate or surface, to which motion is communicated in any convenient manner. The projecting parts of the pins pass between surfaces covered with buff leather, or other suitable material, prepared with oil and emery, or other scouring and polishing materials. The surfaces are caused to travel to and fro in any convenient manner along the length of the pins or needles, whilst they are caused to rotate by the sideway movement of one of the clumping plates or holding surfaces. The knitting or other pins or needles are first acted upon by the surfaces prepared with coarse materials, suitable for scouring off the scale and rough surface of the articles, after which they are operated upon by surfaces prepared with finer materials, for finishing and polishing. When a portion of the length of the pins or needles has been operated upon, they are taken out of the clamps or holding surfaces, and the ends are reversed so as to complete the scouring and polishidg of their entire length. *Patent completed.*

1604. H. Saunders and J. H. Mills. *Improvements in the manufacture of venetian blinds and other window blinds, and in apparatus for raising and lowering the same.* Dated May 28, 1862.

This invention has for its object, in the first place, the construction of the blinds, and the combination therewith of apparatus for raising and lowering the same, in such a manner as to admit of the several laths thereof being packed together at the top instead of at the bottom as usual. For this purpose the several laths are respectively connected to a chain at each end, such chains being adapted to work in gear with a pair of corresponding toothed wheels, by the revolution of which the several links of the blind are successfully carried forward and packed together in a suitable receptacle at each side of the window, being guided into their respective places by means of guides, which are in some cases fixed, and in others moveable on centres. By thus packing the chains, the laths will become packed likewise. In lowering the blinds, the several links of the chains are successfully brought out of their receptacles by the revolution of the wheels, in the direction contrary to that in which they were turned for raising the blind. The laths of the blind are kept at any desired angle so as to admit more or less light by means of spring barrels, with cords fixed to tapes on each side of the blind, such cords being wound on to the barrels on lowering the blinds, and off them on raising the same. By this means, the several laths are kept in correspondiug positions during the raising or lowering of the blind. The invention consists, in the second place, in adapting and applying to venetian blinds, apparatus known by the name of "lazy tongs," for the purpose of causing the laths to approach near together gradually throughout the blind when it is raised, instead of bringing the laths at the bottom of the blind close together, as usual. And the invention consists, in the last place, in fixing the raising and lowering cord of venetian or other blinds so as to run on a spindle inside a tube on the end of the ordinary roller, for the purpose of allowing the blind to extend to or nearly to the whole width of the window, instead of leaving the usual space between the end of the blind and the side of the window. *Patent completed.*

1605. J. Hurst, jun., and E. O. Taylor. *Improvements in means or apparatus for evaporating water and other fluids, and in economizing the use of steam.* Dated May 28, 1862.

The object of these improvements is to obtain a succession of chambers for the passage of the products of combustion from the fire used to heat steam boilers, or other evaporating vessels, adapted to effect repeated separation and re-admixture of the heated products of combustion in their passage from the fire, and a consequent absorption of an increased amount of heat therefrom. For this purpose, the flue space is at intervals, formed into what may be called chambers, with series of valve tubes for the free passage therefrom of the water or other fluid, and adapted to separate the products of combustion, whilst the intermediate parts or chambers are provided with smoke tubes, by which a re-admixture or other separation of the products of combustion is obtained, and so on. And the patentees make the smoke tubes of the succeeding chambers progressively larger than those of the preceding. Passages to the respective chambers are obtainable by the introduction amongst the other tubes of larger tubes, not only from one chamber to the next, but also to the outside of the boiler for repairing or cleaning. They apply the tubes to such and other evaporating vessels, by parts of the ends of such tubes being turned down to pass into holes in the plates to which they are applied, and they form such holes tapered or bell-mouthed, so that the ends of the tubes projecting therethrough may be better spread out therein in rivetting, and sometimes they increase the holding by the application of rings. The improvements relate, secondly, to conducting the smoke to a chamber or casing around the steam cylinders, and they apply scrapers or brushes to keep the surfaces thereof clear, by which heat will be imparted to such cylinders and the use of steam economized. *Patent completed.*

1606. R. A. Brooman. *Improvements in circular looms, or machinery for the manufacture of looped or knitted fabrics.* (A communication.) Dated May 28, 1862.

This invention is not described apart from the drawings. *Patent completed.*

1607. J. H. Johnson. *Improvements in the manufacture of tinned lead pipes, and in the apparatus employed therein.* (A communication.) Dated May 28, 1862.

This invention relates to an improved system or mode of tinning or coating the interior and exterior surfaces of lead pipes made by hydraulic pressure, and consists of a peculiar mode of supplying one or more layers or coating of tin over the lead surface of the pipe, so as to obtain coatings of different thicknesses as desired. This is accomplished by having a reservoir of molten tin placed above the tinning tool, so as to supply the tin constantly thereto. The tin is introduced to the interior of the pipe by an opening in the mandrill, which regulates the diameter of the same, the tin being applied continuously, as fast as the tube is made, either to the interior or exterior thereof. *Patent completed.*

1608. W. Blackmore and H. Lamb. *Improvements in burning limestone and generating steam.* Dated May 28, 1862.

For the purposes of this invention, in order more advantageously and economically to burn the fuel used, whether coal, turf, or peat, when generating steam, limestone is introduced into and burned in the ordinary steam boiler furnace, by which lime is manufactured at a cheap rate, whilst the fuel employed is found to be more effective in generating steam than when burned in the same furnaces without the introduction of limestone. This invention is peculiarly useful when using the furnaces of tubular steam boilers having fire-boxes, such as are usually applied to locomotive engines. In practice, the limestone in lumps is spread over the fire bars of the furnace, and the fire is made thereon, and the fire is kept up by additions of fuel together with quantities of limestone mixed with or thrown on to the fuel therewith. *Patent completed.*

1609. J. A. Ransome. *Improvements in the manufacture of, and in fastening railway chairs with wood trenails.* Dated May 28, 1862.

The patentee claims the manufacture and use in fastening railway chairs of compressed wood trenails, drilled longitudinally from the heads towards the points, but not through the points, in order that they may receive metal spikes in such manner that they shall derive their principal holding power from the expansion of the trenails after they have been driven, substantially as described. *Patent completed.*

1610. J. Critchley. *An improved rib fastener for umbrellas and parasols.* Dated May 29, 1862.

This invention consists in the application of a sliding bush to the stick of the umbrella or parasol, to which bush a cupola-shaped cup is attached; the bush is provided with a slot forming with a stud in the stick a double bayonet joint. When the umbrella or parasol to which the improved fastener is applied is closed, the bush is lowered on the stick to enclose the ends of the ribs in the cupola-shaped cup, and the bush is turned slightly round to bring the angle part of the slot on to the stud which retains the fastener in its place. The fastener is held beyond the ends of the ribs by sliding the bush up the stick of the umbrella or parasol, and securing the angle slot at the other end thereof to the stud in the stick of the umbrella or parasol. *Patent completed.*

1611. J. Hurst, jun., and J. Wood. *Improvements in stereoscopic apparatus.* Dated May 29, 1862.

The object of these improvements is to neutralize the granular, fibrous, and general coarseness of objects seen through stereoscopic glasses, especially when high magnifying powers are employed, and also to produce various changes of effect to such objects. For this purpose the patentees apply tinted media in position that the direct or reflected rays of light falling on the front of the picture may pass through such media, without intercepting the vision. They also apply such media for the passage of the rays of light on to the front of the picture, in combination with other tinted media at a short distance behind the picture, when the picture viewed is transparent, depending upon the magnifying power employed. The media may be tissue paper, gelatine, glass, or other suitable transparent material, and by varying the tints very pleasing changes may be obtained at morning, or evening, or other times of the day or night, summer or winter, or other changes of the season, or of the atmosphere. Also, they apply tinted, transparent, or semi-transparent media at a short distance behind the picture, so as to procure varied effects to the picture when the picture viewed is transparent, by connecting such transparent media by cords, strings, or chains, or otherwise, so that there may be intervals between the respective media when the natural colour of the transparency may be seen. They also apply, in connection with stereoscopic apparatus, a lamp with a shade or shades, lenses, and transparent or semi-transparent media of various tints and shapes, adapted to obtain on the same picture the effects of sunrise and sunset, moonlight, and other periodical or atmospherical appearance. *Patent completed.*

1612. P. Boissett and B. Antognini. *Improvements boots and shoes.* Dated May 29, 1862.

This invention consists in the combination with caoutchouc or india-rubber soles for boots or shoes of a metal piece or pieces, or nuts, with suitable thread holes for the reception of screws, whereby the upper leather and inner soles are securely fastened to the said caoutchouc soles. Further, in the combination with the india-rubber or caoutchouc heel of metal points, to prevent the wearing away of said heel, and likewise in the combination with the india-rubber or caoutchouc heel of a box, or capsel, to attach a spur to the heel. *Patent completed.*

1613. H. Boetius. *A new mode of colouring (refrigerating) hot liquids and condensing steam.* Dated May 29, 1862.

We cannot here quote the details of this invention. *Patent abandoned.*

1614. G. Ashton. *Improvements in dyeing fibrous substances, and in the means or apparatus employed for that purpose.* Dated May 29, 1862.

The patentee claims the method of employing bar-wood or other dye-woods, or wares, in the process of dyeing fibrous substances, by having a perforated false bottom in the dye vessel to prevent the wood or wares coming into contact with the fibrous substances being dyed. *Patent completed.*

1615. J. D. Lee and J. Crabtree. *Improvements in looms for weaving.* Dated May 29, 1862.

This invention consists, 1, In working the shafts or treddles by the ordinary jack rods, in combination with hooked catches and grip levers, or knives, operated by tuppers on the low shafts, the said catches being brought into contact with the said levers by means of peg lags, or other suitable indicating apparatus, aided by springs, by which the inventors obtain a double lift. 2, In working or operating the picking levers by pinions and racks, in combination with double-nosed tappets and moveable friction pullies, which are brought into, or out of, contact with the said noses, as required, by levers and rods, actuated by a changeable chain of tuppers, whereby any number of picks can be made from one end of the loom, in succession, up to the number of change shuttle-boxes employed. 3, In the means of stopping the loom instantly when a shuttle remains in the shed, which is effected by having fingers, so placed as to be operated by the loose reed, and brought into contact with a lever, which acts upon the strap guide, and also against the stops, which prevent the crank-shaft from passing the centres. *Patent abandoned.*

1616. W. Perks. *An improvement or improvements in metallic sash-bars for windows, skylights, hothouses, and other like purposes.* Dated May 29, 1862.

According to this invention, the patentee makes the metallic sash-bars very nearly of the ordinary figure, that is, of the figure, in cross section, of an inverted T; but he makes the top of the vertical rib somewhat thicker than the other parts of the rib. Upon the said vertical rib of the sash-bar he places a folded or doubled metallic strip, which fits upon the said rib and clips it closely, the lower edges of the said double strip being turned into a nearly horizontal plane, so as to cover, or partly cover, the horizontal parts of the sash-bar on which the panes of glass rest. The said folded or doubled metallic strip is fixed upon the sash-bar by its opposite sides being partially separated when it is placed upon the bar and allowed to close, and thereby fix itself. *Patent completed.*

1617. C. D. Abel. *Improvements in apparatus for raising, propelling, or exhausting air, water, or other fluids or gases.* (A communication.) Dated May 29, 1862.

This invention has reference to that class of apparatus for propelling or exhausting air, water, or other gases or fluids, in which the same is impelled forward in a linear direction, by being acted upon by helical or screw blades, or vanes, rotating round a central axis inside a fixed casing. This invention consists in forming the rotating vanes, or blades, of such apparatus of only such a radial depth inwards from the circumference of the casing as to constitute an annular fan-blower, or propeller, acting upon the air, water, or other gas or fluid, which is conducted to the same in the manner hereafter described. The diameter of the casing and fan is enlarged from that of the conducting tubes, so as to present an annular sectional area approximating to the sectional area of the conducting tube. The blades, or vanes, are, by preference, attached to the external circumference of a drum, fixed on the spindle, carrying a pulley, to which rotary motion is imparted; but they may also be fixed to the internal circumference of a loose ring, forming part of the casting, to which ring rotary motion is imparted from the exterior in any suitable manner, by which arrangement an internal spindle might be dispensed with. The invention consists, further, in imparting a peculiar form to the vanes, or

blade, of the fan or propeller; these are placed in an oblique position to the axis of rotation, but, instead of being formed, as usual, entirely as an ordinary screw-blade, the ends only of the blades, or vanes, are so formed, the outlet side having, however, a greater pitch than the inlet side, and the middle portion being formed with a curvature, which is concave, in the direction in which the air, water, or other fluid, is propelled, and the surface of which is generated by a straight radial line, moving in a curved oblique direction, on the surface of the drum. Further, the invention consists in fixing guide vanes, either both on the inlet and the outlet sides of the rotating fan-blower, or propeller, or only on the inlet or the outlet side. Further, this invention consists in conducting the air, water, or other fluid, from the inlet tube to the increased diameter of the annular fan-blower, or propeller, by a conical guiding surface, or "ogival," projecting from immediately below the inner edge, either of the guide-blades or vanes, or of the rotating blades or vanes, when guide vanes are not employed, and terminating in a point; its surface is formed, by preference, with such a curvature as to guide the air easily, and with the least possible obstruction to the revolving vanes. *Patent completed.*

1618. R. GRIFFITHS. *Improvements in marine propellers for ships and boats, and for the sheathing of iron ships with metal sheathing to keep them from fouling.* Dated May 29, 1862.

This invention consists, 1, In constructing screw propellers for steam ships, and boats with blades and centre boss of similar form and construction (or the blades may be cast on the boss) to those described in the specification of a patent granted to the present patentee on the 20th Feb., 1858 (No. 319), but having four blades (or two sets of blades) which are to be fixed either to the same boss or to separate bosses on to the screw shaft, and so fixed that one set or pair of blades is placed before the other set or pair of blades, that set next the shaft to be of larger diameter than the after set, so as to get a greater hold on the water for propelling the ship. 2, Relates to side wheel propellers, which he proposes to construct of discs of suitable diameter, having the centre parts constructed with arms and centres similar to those generally used for paddle-wheels, but having the outside rims of such discs corrugated, or in a zigzag form, instead of being flat, in order to offer sufficient resistance, when driven through the water, to propel the vessel. Either one or a series of these discs can be used on each side of the vessel, as may be required, to propel the ship, or the outside rims may be made flat, and the inside rims only be made corrugated or in zigzag form. 3, Relates to the sheathing of iron ships with copper or other suitable sheets of metal (which sheets being perforated with holes stamped therein) to keep them from fouling, and this he proposes to do in the following manner:—The bottom of the ship should be first well cleaned and painted over with one or more coats of red lead paint, or any other suitable material, to preserve the iron. He then covers the part required to be sheathed with metal sheathing with some prepared adhesive material, such as a mixture of tar, pitch, or other suitable substance, and upon that he lays a coating of felt, gutta percha, or other suitable materials, and on that he again places another coating of adhesive materials, upon which he places the perforated metal sheathing, which is made warm on being applied to the ship's bottom, and is pressed on to the adhesive material until it comes through the perforated holes made in the metal sheathing. Or the holes can be filled with stout metal nails, made rough so as to set and fix themselves in the adhesive materials. He then proposes to solder, fold, or overlap the edges of the sheathing sheets together, and to line the sides of the ship at or above the water line with a cleating of wood, well secured to the vessel, so as to protect the covering and adhesive materials, and to which he secures the edges of the sheathing metal with sheathing nails. He also proposes, if necessary, to place narrow pieces of elastic substances (or strips of wood), well secured to the ship, along the ship's side, at suitable distances apart, to which he fixes the sheathing with nails, in the same manner as above proposed to the cleating. *Patent completed.*

1619. J. PATERSON. *An improved hemmer or instrument for turning over the edges of a binding or strip of linen, or other materials, and preparing it for stitching in sewing machines.* Dated May 29, 1862.

This improved hemmer consists of a conical plate of metal, the edges of which are folded over on each side from the centre into a double fold; from the back part of the plate the edges are removed. The hemmer is fixed on its side upon a bed plate, and at the rear of the hemmer the patentee fixes an upright with a spring. *Patent completed.*

1620. W. CLARK. *Improvements in throwing the shuttles of looms.* (A communication.) Dated May 29, 1862.

This invention relates to an improved method of throwing the shuttle a given distance at a uniform and regular speed, by the application of the attractive force of the magnet, or electro-magnet, as a motor; thus a shuttle is furnished wtih an iron armature, acted on by a magnet or electro-magnet placed in proximity to it, and having a suitable motion imparted to it at a given speed, which will be thence transmitted to the shuttle. The advantages of employing this improved method of driving the shuttles are—1, Prevention of all jerking and consequent rupture of the threads. 2, Counteraction of the dead weight of the shuttle, which permits of its carrying an additional amount of thread. 3, The shuttle never stops at any point of its traverse. 4, Great saving of time by reason of its uniform motion, uninterrupted by any rupture of the thread or stoppage of the shuttle. 5, The weaving may be effected with much more uniformity than formerly. 6, The capability of weaving all kinds of fabrics, the widths of which will be limited only by the size of the other parts of the loom, independently of the throw of the shuttle. 7, In this manner fabrics of great width may be woven, thereby obviating the necessity of having joins or seams. The motion of the shuttle may be produced by the influence of the electro-magnetism alone constituting the motive power, or it may be obtained by the aid of a self-acting apparatus, and thus form a self-acting shuttle. *Patent completed.*

1621. N. LAWTON and R. P. WHITWORTH. *Improvements in engines for carding cotton and other fibrous materials.* Dated May 29, 1862.

This invention relates to the mechanism for removing the fibrous material from the doffers, and to that arrangement for this purpose, wherein the doffer comb is secured to a shaft passing in front of the doffer, the shaft receiving oscillations from a crank or eccentric working directly into a slotted lever or arm on the end of the comb shaft. The improvements consist in the peculiar construction and arrangement of the above desired mechanism. The patentees strengthen the shaft to which the doffer comb is attached by a rib on that side of the shaft opposite to the comb, so as to resist the bending action put upon it by the screws, by which the comb is kept tightly stretched. They form the pulley in which the crank or radius-pin is fixed, and its axis, all in one piece, or they fix the pulley on a short shaft, and arrange it so that it can rotate in a bearing cast in one of the brackets supporting the ends of the comb shaft. The crank pin is formed by a set screw which screws into the side of the said pulley, and this said set screw passes through a bush having a collar formed upon it; this bush passes through, and can rotate, freely in a hole made through a die, which can slide freely in the slotted cain on the end of the comb shaft. The sliding die has two recesses, into which pieces of leather or other similar material is inserted, this leather working against the slides of the slot in the slotted arm. The slotted arm is placed so as to descend vertically or thereabouts from the end of the comb shaft when it is at its mid oscillation, and a hole is drilled from the upper side of the boss of the slotted arm into the upper end of its slot, and by this means oil can be supplied to the sliding die at any time without stopping the engine. For very quick speeds they sometimes use a bowl in place of the sliding die. *Patent completed.*

1622. S. MINTON. *An improved construction of revolving batteries.* Dated May 29, 1862.

This invention relates to improvements on the floating rotating battery, for which the present inventor obtained, in conjunction with Richard Handley Thomas, letters patent, dated April 3, 1858 (No. 715). In the specification of that patent, in order to facilitate the turning of the shot-proof chamber containing the guns, he showed and described a deep tank for receiving a water-tight compartment or caisson, forming part of a rotating chamber. The caisson portion was situate below the gun platform, and was immersed in water in the tank, thus giving the chamber the requisite amount of buoyancy. This elongation of the chamber and the deep tank for receiving it was for the sole purpose of giving buoyancy to the battery, and involved a considerable outlay for its manufacture. He now proposes materially to reduce the depth of the caisson and tank, and to obtain the requisite buoyancy by the use of mercury in place of water. The ventilation will be at the top, and access may in general be conveniently gained to the interior of the battery by a central hollow shaft, around which the annular portion of the chamber revolves. *Patent abandoned.*

1623. W. FOOTMAN. *Improvements in the treatment and use of sewage and liquid manure, and in reservoirs and pipes to be used therein.* Dated May 30, 1862.

The nature of this invention consists, 1, In constructing tanks or reservoirs to receive the sewage, and to effect a separation of the liquid from the floating and sedimentary matter contained therein. 2, In laying down an inlet system of underground pipes for manuring the land with liquid manure, in conjunction with an outlet system of underground pipes for draining the land from water. 3, In the manufacture of the said underground pipes to be used for the above purposes. *Patent abandoned.*

1624. J. DATICHY and E. SABATIER. *Improved machinery and process for making pulps for the manufacture of paper and other purposes.* Dated May 30, 1862.

This invention consists of new and improved machinery and apparatus for converting rags, and all kinds of textile and fibrous matters suitable for the purpose, into pulp, stuff, or pile, for the manufacture of paper, papier mache, and other purposes; and it also consists of a new and improved process which is therein applied, and which the patentees denominate the dessicated process. The new and improved machinery comprises,—1, A stove, or inclosed chamber, in which the raw material is subjected to the regulated heat. 2, A new (dry action) cylinder machine, which consists of a large fluted cylinder, rotating upon its axis, and giving motion to a number of small-cylinders, or rollers (also fluted), and by which the large cylinder is partially surmounted; between the large and smaller cylinders the materials are subjected to a peculiar semi-crushing and semi-grinding process. 3, A mill, with a suitable hopper, for receiving the materials from (and partly prepared by) the cylinders. By this mill the materials are reduced to a fine lint-like fibrous or pile state; this completes the first stage, or dessicated process. The material thus prepared is then further treated as follows:—From the mill last mentioned the stuff falls into a cistern, or vessel, containing a suitable dilute, or chloriated water, in which it is steeped for a short time, and is thence drawn through an air-tight conduit into an exhausted steaming cylinder, which is fitted internally with disc agitators, and is also in connection with a boiler, or steaming apparatus. In certain cases, however, the steeping cistern may be dispensed with, and the materials from the mill may be run directly into the cylinder in which the chloriated or other liquid may be placed, and the first bleaching operation performed. The materials in the state of pulp are now subjected to a rapid motion and a volume of steam simultaneously, and are then removed into a second bleaching, or washing and cleasing, cylinder, in which they are finally dried, by exhaustion and pneumatic action. *Patent completed.*

1625. P. W. PAYRAS. *A system to protect all dry skins from vermin.* Dated May 30, 1862.

This invention consists in a process, the effect of which is to preserve, for an indefinite period, skins or hides of every description, whether dry or green, protecting them infallibly from the attacks of vermin, and, consequently, suppressing the operations of beating and salting. For this purpose, the patentee uses a mixed solution of sulphate and chlorure of zinc, marking 15 degs. by Beaume's aerometer, sometimes adding from eight to ten grains of arsenic for every quart of this liquid. The presence of the arsenic not being essentially necessary, he reserves the option of using or not using this body. From its simplicity, the application of the process is exceedingly easy, and does not necessitate the use of any plant, the cost of which need be taken into consideration. In fact a trough, or simply a stone vat, into which the liquid above mentioned is introduced, constitutes the entire plant. The operation is then effected by applying, with a brush or otherwise, a coating of the liquid on that part of the hide only which has adhered to the flesh. To operate more rapidly the hides may be immersed in the liquid, and this method is most preferable for hides with hair. *Patent completed.*

1626. J. GURRIN. *Telegraphic communication between separate buildings or parts of buildings.* Dated May 30, 1862.

This invention is not described apart from the drawings. *Patent abandoned.*

1627. R. NICHOLSON. *Improvements in the construction of lawn-mowing machines.* Dated May 30, 1862.

This invention relates to the delivery of the grass which has been cut by the cutting portion of the machine, and consists of a self-acting apparatus whereby the grass when cut is delivered with great facility. An endless belt passes over three rollers actuated by a shaft fitted with universal joints, the same being geared to a pair of bevel wheels on the roller or drum shaft of the machine. The grass as it is cut falls on the said endless belt, and a double clutch and lever handle fitted to the bevel wheels being provided, the apparatus is entirely under the control of the operator, who can, by moving the lever handle either to the right or left, deliver the grass to either side of the machine without stopping the same. *Patent abandoned.*

1628. J. LEON. *A stopping rein.* Dated May 30, 1862.

This invention consists in a curb or rein with an under throat piece for enabling riders or drivers to stop restive or run-away horses. This rein, which the rider holds with his little finger, is passed into a martingal with rings placed on each side of the horse's collar, then through two rings fixed on each side of the piston snaffle; this rein rises under the throat of the horse, and passes into two rings carried by the head stall. For horses harnessed to a carriage, the stopping rein is passed into two screw rings fixed to the seat, then through the rings of the snaffle and ring, and so as to pass into the rings of the headstall, and finally rests under the throat of the horse. This rein may be flat at the part held by the driver, and round at that part which is to move in the rings, which may be furnished with rollers or replaced by small pulleys. The conductor has only to pull the rein to produce a pressure under the horse's throat sufficiently great to prevent, if required, the air from entering his lungs; hence it will always be possible to stop a horse. *Patent abandoned.*

PROVISIONAL PROTECTIONS.

Dated Oct. 17, 1862.

2803. J. Summerton, Smethwick, agricultural machinist. Certain improvements in harrows for harrowing land.

Dated Oct 29, 1862.

2912. W. Clark, 53, Chancery-lane, engineer. Improvements in apparatus for ascertaining and recording the speed and distance travelled by vehicles, the flow and quantity of water, and other analogous purposes. (A communication.)

Dated Nov. 6, 1862.

3007. W. N. Hutchinson, Plymouth, Major.General. Improvements in apparatus or means for protecting the screw of steamers from becoming entangled with or fouled by ropes or other bodies.

Dated Nov. 12, 1862.

3047. T. Bradford, Cathedral-steps, Manchester, washing machine manufacturer. An improved clothes wringer and mangler, applicable to pressing the liquid from clothes in the process of washing and other pressing purposes.

Dated Nov. 13, 1862.

3055. G. W. Rendel, Newcastle-on-Tyne, civil engineer. An improved method of strengthening armour plates made of carbonized iron or steel.

Dated Nov. 20, 1862.

3120. J. W. Child, Halifax, engineer. Improvements in means and apparatus for working wool and other fibres.

Dated Nov. 21, 1862.

3131. J. Steart, St. James's-road, Blue Anchor-road, Bermondsey, manufacturer. An improved method of extracting the fibre from zostera marina and other aquatic vegetable productions.

Dated Nov. 24, 1862.

3155. W. Tatham, Rochdale, machine maker. Improvements in machinery or apparatus for preparing and spinning cotton, wool, flax, and other fibrous materials.

Dated Nov. 25, 1862.

3166. W. Longley, builder, Leeds. Improvements in machinery for making bricks.

Dated Nov. 27, 1862.

3177. A. A. Phéloux, 75, Rue Quincampoix, householder, and P. A. Paumier, 9, Rue Christine, merchant, Paris. A new atmospheric sailing propeller.

3179. T. Keyworth, Blue Court, Boston, Lincolnshire. Improvements in motive power machinery.

3183. D. Veerkamp and C. F. A. Van Trigt, 11, Mercers-terrace, Limehouse. Improvements in the treatment of old manufactured fabrics, in order to obtain useful fibrous products therefrom.

3185. W. Clark, 53, Chancery-lane, engineer. Improvements in gas burners. (A communication.)

Dated Nov. 28, 1862.

3186. J. Carbonell, 15, Passage des Petites Ecuries, Paris, merchant. Improvements in preparing, manufacturing, and washing the paper pulp derived from the esparto plant, and in apparatus connected therewith.

3187. W. A. Waddington, 44, Stonegate, York, pianoforte maker. Improvements in machinery for cutting wood.

3189. J. H. Johnson, 47, Lincoln's-inn-fields, gentleman. An apparatus for indicating the pressure of electric conductors in foreign bodies. (A communication.)

3191. J. Cresswell, Birmingham, undertaker, and E. T. Greves, gentleman. Improvements in the construction of hearses and funeral carriages.

3192. S. J. Browning, Portsmouth, engineer. Improvements in machines to be employed in brewing.

3193. W. Clark, 53, Chancery-lane, engineer. Improvements in the permanent way of railways. (A communication.)

3195. J. F. Delany and J. C. R. Okes, Victoria Foundry, Greenwich, engineers. Improvements in double cylinder expansive steam engines.

Dated Nov. 29, 1862.

3199. T. Blackburn and M. Knowles, Blackburn, machine makers. Improvements in looms for weaving.

3200. F. G. Taylor, Manchester, machinist. Improvements in washing machines.

3201. J. Crompton, Bolton, machinist. Improvements in machinery or apparatus for ploughing, harrowing, clearing, and drilling land.

3204. W. Clark, 53, Chancery-lane, engineer. An improved machine for cutting corks and other stoppers. (A communication.)

3205. F. Vacher, Parliament-street. Improvements in ornamenting playing cards.

3207. The Rev. H. Moule, Fordington, Dorset, clerk, master of arts. Improvements in locomotive engines, and in apparatus for generating steam for steam engines.

3209. J. Anderson, C.E., Royal Arsenal, Woolwich. Improvements in the manufacture of the tyres of railway wheels, and rails, switches, and crossings of railways.

3211. M. Henry, 84, Fleet-street, patent agent. Improvements in the manufacture of leather. (A communication.)

Dated Dec. 1, 1862.

3213. P. Bourne, Whitehaven, colliery viewer. Improvements in miners' lamps.

3215. T. Waller, Fish-street-hill, stove manufacturer. Improvements in stoves.

3217. R. Flude, Aylestone-street, Leicester. Improvements in looms for weaving narrow fabrics.

3219. J. Romer, Shipbourne. Improvements in the manufacture of bullion wire and metallic fine drawn wire.

3220. W. Clark, 53, Chancery-lane, engineer. An improved apparatus applicable as a pump, water meter, hydraulic motor, or a steam engine. (A communication.)

3221. P. W. Reuter, Buckland-crescent, St. John's Wood, merchant. The preparation of a new compound to be used for dyeing and printing purposes. (A communication.)

3222. E. D. Johnson, Wilmington-square, watch and chronometer manufacturer. Improvements in pocket watches.

Dated Dec. 2, 1862.

3225. H. Twelvetrees, Bromley, manufacturer. Improvements in apparatus for cleaning knives, forks, and boots.

3227. H. Twelvetrees, Bromley, manufacturer. Improvements in washing, wringing, and mangling machines.

3230. G. F. Blumberg, Cannon-street West, manufacturer. An improved method of, and apparatus for, producing designs in or on glass.

3231. J. Wheatley, 9, Glücks Strasse, Munich, captain. Improvements in the construction of ships of war, and in the manufacture of armour plates for ships, forts, and batteries.

3233. G. T. Bousfield, Loughborough-park, Brixton. Improvements in forming the permanent ways of railways. (A communication.)

3234. G. T. Bousfield, Loughborough-park, Brixton. Improvements in apparatus for discharging guns or ordnance. (A communication.)

3235. D. Graham, Edinburgh, commander. Improvements in steering and manœuvring ships or vessels, and in the apparatus employed therein.

3237. R. K. Cautley, Thorney, Cambridge, gentleman. Improvements in electro thermal baths. (A communication.)

3239. B. Browne, 49, King William-street, civil engineer. Improvements in the construction of knobs or handles of door locks, and in the mode of connecting same with the sliding bolts thereof for advancing and drawing back said bolts. (A communication.)

Dated Dec. 3, 1862.

3241. A. T. Becks, Birmingham, iron master. Improvements in machinery for cutting or shearing sheets or plates of metal.

3243. C. F. Claus, Fearnhead, chemist. Improvements in carboy hampers, and in the machinery or other means used for manufacturing the same.

3244. A. Morton, Arbroath, Forfar, engineer and machinist. Improvements in lawn-mowing machines.

3245. W. H. Browne, 29, Alwyne-road, Canonbury. Improvements in gas stoves.

3247. A. F. Eden, Threadneedle-street, optician. Improvements in apparatus for taking minute photographic pictures and magnified pictures of microscopic objects.

Dated Dec. 5, 1862.

3261. T. E. Blackwell, Orsett-terrace, Hyde-park, civil engineer. Improvements in barometers or instruments for measuring altitudes, or the pressure of the atmosphere or elastic fluids.

3268. F. Walton, Wood-street, City, manager. An improved article of wearing apparel for the neck.

Dated Dec. 6, 1862.

3272. J. and M. Craig, Kilmarnock, fire clay manufacturers. Improvements in apparatus for the manufacture of clay.

3274. W. McNaught, St. George's Foundry, Rochdale, engineer. Improvements in machinery for washing and drying textile fabrics and materials.

3276. J. Burchall, St. Helen's, Lancaster, merchant, and E. Borrows, Sutton, engineer. Improvements in propellers for ships and other navigable vessels.

3278. R. McClintock, Dublin. Improvements in carriage axles.

Dated Dec. 8, 1862.

3286. R. A. Brooman, 166, Fleet-street, patent agent. Improvements in kneading machines. (A communication.)

3288. C. Sanderson, Sheffield, steel manufacturer. An improved mode of manufacturing bands for driving machinery, lifting weights, and other analogous purposes.

3290. J. Hilliar, Balsall Heath, Worcester, manager. Improvements in hinges, joints, or connections, and in applying them, parts of which improvements may also be employed for constructive and decorative purposes.

Dated Dec. 9, 1862.

3296. V. Mirland, Frameries, Belgium, manufacturer. Improvements in manufacturing paste with the dried pulp of rhubarb to be used as preserve.

3298. W. Clark, 53, Chancery-lane, engineer. Improvements in photographic apparatus. (A communication.)

3300. G. Jeffries, Golden Ball-street, Norwich, gun maker. Improvements in breech-loading firearms.

3304. W. E. Newton, 66, Chancery-lane. Improvements in firearms. (A communication.)

Dated Dec. 10, 1862.

3310. S. B. Whitfield, Birmingham, manufacturer. Improvements in the dovetail joints used in metallic bedsteads and other articles of like manufacture.

3314. W. A. Turner, Lawrence Poutney-lane. Improvements in machinery for cutting or paring starch.

Dated Dec. 11, 1862.

3320. J. R. Breckon, Darlington, accountant and manager, and T. Douglas, Peases West Colliery, Crook, Durham, colliery viewer. Improvements in the manufacture of fire bricks and other articles usually made from fire clay.

3322. R. Clark, Langloan, North Briton, engineer. Improvements in machinery or apparatus for boring, winding, and lifting for mining purposes.

3324. J. Imray, 65, Bridge-road, Lambeth, engineer. Improvements in apparatus used for mixing and kneading.

3226. T. E. Vickers, Sheffield, in the county of York, manufacturer. Improvements in the construction of ordnance.

The full titles of the patents in the above list can be ascertained by referring back to their numbers in the list of provisional protections previously published.

Opposition can be entered to the granting of a patent to any of the parties in the above list who have given notice of their intention to proceed, within twenty-one days from the date of the *Gazette* in which the notice appears, by leaving at the Commissioners' office particulars in writing of the objection to the application.

LIST OF SEALED PATENTS.

Sealed December 19, 1862.

1850. W. Hargreaves and G. H. Leather.	1891. A. A. Croll.
1851. T. Carr.	1897. G. H. Hulskamp.
1868. J. Whitham.	1898. J. Garnier.
1869. G. Turner.	1901. J. Tatham.
1876. J. Parkes.	1902. J. Petrie.
1882. J. Watson.	2585. C. Mertens.
1888. R. A. Brooman.	2693. T. Keech.
1889. A. H. Martin.	2754. C. McCarthy.
1890. I. Holden.	2805. J. and G. Davies.

Sealed December 23, 1862.

1905. J. Wall and T. Dodd.	2080. A. Fournier.
1906. W. Thomas.	2096. A. Vignon.
1922. J. M. Dunlop.	2121. T. Sagar and J. Rocliff.
1943. J. Miles.	2237. H. B. Barlow.
1973. A. Gilbey.	2627. C. D. Abel.
1976. C. F. W. Rust.	2667. G. J. Firmin.
2009. J. H. Johnson.	2736. H. A. Marinoni.
2042. R. Dunn.	2935. G. Haseltine.
2064. W. E. Newton.	

PATENTS ON WHICH THE STAMP DUTY OF £50 HAS BEEN PAID.

2883. G. S. Goodall.	2906. J. H. Johnson.
2898. G. and J. Collier.	2950. T. S. Truss.
2900. W. Henderson.	2975. T. S. Cressy.
2496. W. E. Newton.	2892. J. Fairclough.
2896. J. Willcock.	2909. S. Plimsoll.

PATENT ON WHICH THE STAMP DUTY OF £100 HAS BEEN PAID.

2902. J. Chesterman.
